THE

ENGLISH CYCLOPÆDIA.

ARTS AND SCIENCES.

F is a labio-dental aspirate bearing the same relation to the other labio-dental aspirate V which the letters called *tenues*, *p*, *k*, *t*, bear to the *mediæ*, *b*, *g*, *d*. It occupies the sixth place in the English as in the Latin alphabet, thus corresponding with the digamma of the old Greek alphabet, and the vau of the Hebrew. In power and form it is likewise closely related to those two letters. [ALPHABET.]

The letter F is interchangeable with the other aspirates *ch* or *h* and *th*, and also with the lip-letters *p* and *b*.

1. F in Latin corresponds to *h* in Spanish, as Latin *formoso*, beautiful, Spanish *hermoso*; Latin *femina*, female, Spanish *hembra*; Latin *fugere*, fly, Spanish *huir*. Other examples may readily be found in a Spanish Dictionary under the letter *h*. The same change prevailed between the Latin of Rome and the Sabine dialect of that language.

2. F in Latin corresponds to *th* in Greek, as Latin *fera*, a wild beast, Greek *θηρ*. Latin *fle*, weep, Greek *θρε*, as seen in *θρηνος*. Indeed this interchange prevailed among the dialects of the Greek language itself as in **ουφαρ** and **ουθαρ**; **φλαν** and **θλαν**; **φλιβω** and **θλιβω**. This however seems to depend on the proximity of the letters *l* and *r*. (See L.)

3. F in Latin corresponds to *b* in German and English, as *frang-ere*, brech-en, to break; *frater*, bruder, brother; *fago*, buche, beech, &c.

4. F in English and German to *p* in Latin, as *pelli*, fell, fell (comp. fellmonger); *ped*, fuss, foot; *pug-na-re*, fechten, to fight, &c.

FABLE, Fabula in Latin, in its general sense means a fictitious narrative, but it also means more particularly a species of didactic composition, consisting of a short fictitious tale inculcating a moral truth or precept. As such it is divided into two sorts, the parable and the apologue. The former narrates some incident, which, although it may not have happened exactly as the narrator supposes, yet could have happened at any time, there being nothing impossible or improbable in it. Of this description are many of the parables contained in the Scriptures, and especially in the New Testament, it being a favourite mode with our Saviour of illustrating his precepts by similitudes. When, for instance, he spoke of the master who, before setting out on a long journey, intrusted certain talents or sums of money to each of his three servants, he did not mean that such a fact had occurred at any particular time, though it might have occurred, but he chose this figure as presenting the ways of God with regard to the mental or spiritual talents he has gifted men with, and which he expects them to cultivate and render useful in proportion to their capacities. The second species of moral fable, called apologue, relates facts which are evidently untrue, and cannot have happened; such as animals, or even inanimate things, speaking, but which serve as comparisons for the actions of men. Such was the well-known apologue of Menenius Agrippa, addressed to the plebs of Rome, who had revolted against the patricians, in which he told them of the various limbs of the human body having once revolted against the belly. (Livy, ii. 32.) Most of the fables which are called Æsopian are apologues, although some are of the parable kind; for example, that of Æsop and the villain who threw a stone at him. (Phædrus, iii. 5.)

The apologue is one of the oldest forms of composition, being well calculated to strike the minds of men in a rude state. Homer's War of the Mice and the Frogs is a composition of the nature of the apologue; only being extended to a considerable length, and including a succession of incidents, it is classed among the heroico-comic poems, whilst the apologue, or fable properly so called, points out only one particular incident from which it draws a moral. In the same manner, in modern times, the 'Animali Parlanti,' or 'Court and Parliament of Beasts' of Casti must be classed among the mock epic poems, although it may be said to consist of a series of apologues, each pointing to some particular error, or abuse, in the state of society, and in the conduct of men. It is probable that the older and simpler mythological fables of the gods and heroes among the ancients were originally intended by the early patriarchs or priests to illustrate by allegory the attributes of the Creator, the phenomena of nature, and the progress of social life; but that in course of time people lost sight of the moral, and believed the fiction in its literal sense.

The oldest collection of fables in any European language is in Greek prose: the fables are attributed to Æsop, but much doubt exists as to the real author or authors of them. [ÆSOPUS, IN BIOG. DIV.] Babrius wrote a metrical version of Æsopian fables, some of which were used as materials for prose versions of the Æsopian fables by the mediæval writers; a few were always common, and a large addition to them was recovered by Minoides Minas, and published in Paris in 1842. [BABRIUS, IN BIOG. DIV.] The fables called the fables of Bidpai or Pilpay [PILPAY, IN BIOG. DIV.] are derived from a collection in the Sanscrit language, and Lokman is said to have written fables in Arabic; but several of the fables attributed to the latter appear to be the same as some of those attributed to Æsop, and it has been supposed that Lokman and Æsop were one and the same personage. [LOKMAN, IN BIOG. DIV.]

Among the Latins, Phædrus, who lived under Tiberius, is the most celebrated: he professes to have taken his subjects from Æsop. The MS. of Phædrus was not discovered before the end of the sixteenth century. Avianus, or Avienus, who (supposing the two names to mean the same individual) lived under the elder Theodosius, wrote a collection of fables in Latin verse. ('Avienus,' Leyden, 1731, with a 'Dissertation on the Identity of Avianus and Avienus.') Faerno of Cremona, who lived about the middle of the sixteenth century, made a collection of Æsopian fables, which he turned into Latin verse, and which were published at Rome after his death in 1564. He was accused of plagiarism, as having found a MS. of Phædrus in some library, and borrowed his subjects from it. The fables and fable narratives of the middle ages have been well described, and their characteristics discussed, by Jacob Grimm, in a preface to his edition of 'Reinhart Fuchs,' published in 1840.

Among the original writers of fables or apologues, in the modern languages, La Fontaine may be fairly placed at the head. Among the English, Gay and Moore have written fables. The Germans have had Lessing, Gellert, and others, and the Spaniards Yriarte and Samaniego. Among the Italians, Firenzuola, Crudeli, Baldi, Capaccio, in the 16th and 17th centuries, wrote chiefly translations or paraphrases from the Greek and Latin fabulists. In the 18th century Pignotti, a native of Tuscany, wrote original fables in verse, which were published at Pisa in 1782, and have been often reprinted since. Bertola also wrote fables (Pavia, 1788), with an essay on fables. Luigi Fiacchi published, under the name of 'Clasio,' a collection of fables (Florence, 1807).

FAÇADE, in architecture, a French term of modern introduction into the English language. It expresses the face or front view of an edifice, as the façade of the Louvre, or the façade of St. Peter's at Rome. Façade was applied originally to denote the principal front of a building. The Italians apply the term Facciata for the most part to such fronts as have a principal entrance.

FACIA, a term used in architecture, or in ornamental construction, to express the subordinate bands of an architrave or of a frieze. It is worthy of notice that in the best examples of Grecian or of Roman architecture the facias are made to incline inwards from the vertical line; as, for instance, in the Parthenon, the temple of Bacchus at Rome, the Baths of Diocletian, and the temple of Vesta at Tivoli. The facias of the architraves of the temple of Mars Ultor, and of the Forum of Nerva, incline outwards; but the optical effect thus produced is so unsatisfactory that it may almost be considered to be indispensable that the more general rule should be observed.

FACTOR is a mercantile agent who buys and sells on behalf of others, usually being intrusted with possession of the goods, to deal with them in his own name, and to receive and give receipts for the money, and is remunerated for his services by a percentage on the transaction. A broker acts as a middleman only, having no possession of the goods, and properly negociating the business in the name only of his principal; the price does not pass through his hands, but he too is remunerated for his assistance by a percentage on the transaction.

No small share of the business of the mercantile world is carried on through the medium of factors, living at a distance from their principals; whom for their own interest they keep duly informed of the state and prospects of the market in their immediate district; and from whom they accordingly receive consignments, often remitting their acceptances for the same in advance, on the expectation that future sales will put them in sufficient funds to retire their acceptances when due. As these transactions multiply, the relation of principal and agent becomes more complicated in interest, and a clear and complete statement of credits and debits on his principal's account is one of the most essential duties of the factor, which a court of equity will compel him to render, if need be, and for want of which, when refused, an action for damages will lie against him at common law.

The law gives him a lien upon the property in his hands for the general balance, composed of advances, expences, and commission, due from his principal; and the produce of sales, as well as the goods before sale, are subject to this lien. He may therefore think it prudent for his own behalf to effect an insurance on the property of the principal in his hands; and unless he is expressly forbidden he may insure in his principal's name, and at his expense; but if the principal requires him to do so, it then becomes his duty, and negligence as to that might leave him answerable for the consequences of accidental fire. He has an interest obviously in keeping the property safe. The law imposes on him the duty of exercising ordinary care and diligence for its protection, but if there is no failure therein upon his part, he is not liable for damage happening to it through violence or accident, as by robbery, or fire, which a prudent, careful man under the circumstances could not have prevented.

In his transactions about the goods of his principal in the market he is bound by the usage of trade, when that is not expressly negatived by his instructions. If it is not usual therefore to sell on credit, and if he yet does so, he is answerable for the consequences of this deviation from his authority. In other respects he is bound to exercise ordinary skill, caution, and diligence, in the discharge of his duties as factor.

By the common law of this country the factor has no authority to pledge the goods of his principal. The disadvantage of this rule with regard to a class of agents who are in the daily habit of binding themselves by their acceptances in favour of the principal, in dependence upon the market and their ability to realise the goods in time to meet the bills at maturity, became so obvious, that the British legislature twice interfered by statute, the 6 Geo. IV. c. 94, and the 5 & 6 Vict. c. 39, to place these agents, in this respect, upon a footing suitable to the necessities of trade and the dictates of prudence. The results of this legislation now are, that a factor may pledge goods or documents of title in his possession for advances to himself, with security to the lender, provided the advances, which must not include an antecedent debt, were bonâ fide, and that the lender had no notice of the pledge being contrary to the factor's authority, or made *malâ fide* in respect of his principal. If the loan is made on a written contract to deposit goods, a pledge in accordance therewith is protected, unless the lender have notice of the factor's want of authority prior to the receipt of the goods; and even an antecedent debt is a good consideration for the pledge to the extent of the factor's lien against the principal, if the pledgee at the time did not know of the factor's agency. Goods or documents of title already on pledge may be replaced by other goods or documents of title in the hands of the pledgee, subject to the continuing lien. Documents of title are now said to be intrusted to the factor, so as to entitle him to pledge them whether they come immediately from the owner or in virtue of his having had possession of the goods or of some other documents of title before.

A sale by a factor creates a contract between his principal and the buyer, and the principal may maintain an action against the purchaser for the price, or by notice may direct him not to pay the money to the factor, which is binding on the purchaser, except in so far as the factor has a lien upon the money against his principal. In the absence of any such notice payment to the factor is a good discharge of the debt. By a purchase through a factor in his own name the seller has the option, as soon as he knows the name of the principal, of taking either the factor or his principal as his debtor in the transaction. But if a bargain is effected with a factor under the opinion that he is a principal, and with a view to a right of set-off which the other has against him, the disclosure of the real principal is not suffered afterwards to deprive the other of his right of set-off.

The principal may recover against his factor by action for the neglect of his duty, or disobedience to his instructions if loss occur thereby, as if he purchases goods at a limited price, and fraudulently sells them again for his own profit. If a factor, without the orders of his principal, exports goods prohibited by the Customs' laws, and the same are seized, the loss is the factor's; and so, if he pay money without the direction of his employer, or sells his goods at an undervalue, or exports goods of an improper quality, he is answerable for the damage. And if a factor exports goods of a different quality or kind from those he was directed to purchase, or sends them to a place other than that to which he was ordered to send them, the merchant may refuse to accept them, and may recover any damage he has sustained, in consequence of his neglect, from the factor. The rights and liabilities of merchants and factors are governed by the laws of the place in which they are domiciled, and any contract which may be made by either of them must be governed by the law of the place where it is made, and these rules are acted upon by the courts of justice of every civilized nation. Thus, since the passing of the above-mentioned statutes, a foreign merchant cannot recover his goods from the pledgee of his factor in England, though he be totally ignorant of the change which has taken place in the law.

There is another description of factor, who acts under what is called a del credere commission, where, for an additional percentage, he engages for the solvency of the purchasers of the goods consigned to him. This contract, it is evident, arises on the supposition that the factor being resident among the purchasers, must be better able to judge of their solvency than the principal, residing in a foreign country. For a long time it was considered that under this arrangement those who dealt with the factor were liable to him alone, and that he was liable, in the first instance, to his employer; it has, however, been decided that the factor stands in the relation of a surety for the persons with whom he deals on account of the employer, and that he is liable to his employer only in case of their default. Del credere is an Italian mercantile phrase, of the same signification as the English word guarantee, and the Scotch warrandice.

(See Russell on *Factors;* Story on *Agency; Id.* on *Bailments;* Sir Wm. Jones on *Bailments;* Paley on *Principal and Agent;* Chitty on *Contracts*, by J. A. Russell.)

FACTOR, a name given to any algebraical expression considered as part of a product. Thus, a and $a+x$ are the factors of the product $a\,(a+x)$, or $a^2+a\,x$.

Any quantity may be made an apparent factor of any other. Thus in

$$a = b \times \frac{a}{b}$$

b is an apparent factor of a. But b is not properly called a factor of a, unless it happen that when b is made $= 0$, $\frac{a}{b}$ is not thereby made infinite. Thus the two equations

$$\sin x = x \times \frac{\sin x}{x}\,, \quad \sin x = x^2 \times \frac{\sin x}{x^2},$$

show x and x^2 as apparent factors of $\sin x$. But x is a real factor; x^2 is a fictitious factor. When

$$x = 0,\ \frac{\sin x}{x} = 1, \text{ and } \frac{\sin x}{x^2} = \infty.$$

FACTORIALS. The subject treated under this word is one which daily becomes of more importance in mathematical analysis, and takes its rise at the commencement of algebra.

When we first begin to number, we easily make the transition from integers to fractions, because we are accustomed to consider ourselves as reckoning simple magnitude, of which each unit can be divided into parts homogeneous with itself. [NUMBER.] Be the unit what it may, in the case of simple magnitude, it might as well have been any fraction of what it is, so far as the possibility of conceiving and performing arithmetical operations is concerned. But when we come to count *operations*, not *magnitudes*, the case is much altered; we can no longer say at pleasure that we can conceive or introduce fractions. Certainly, as to additions, we think we need not stop to learn what a fractional number of them means. If, after having thought for a moment of six additions of 20 and seven additions of 20, we ask ourselves what ought to be meant by *six and a half* additions of 20, we imagine that it must necessarily mean six additions of 20, followed by an addition of 10. But this notion, though the most simple, and therefore adopted as a basis, is not necessary. The algebraist knows very well that having proved the equation $\phi(x, m) = x + mb$ to be true whenever m is an integer, he has not proved it to be true when m is a fraction: in fact, $\phi(x, m) = x + mb \cos 2m\pi$ would equally satisfy his demonstration, and an infinite number of other solutions might be named.

When we come to reckon numbers of multiplications, we begin from unity, and say, let a^n signify that unity is multiplied n times following by a. Now this symbol is, from the beginning, distinctly conceivable, whether a be integer or fractional, under the usual and easy extension to fractions of the idea of multiplication; but it is not, or ought not to be, so intelligible when n is a fraction. What are four and a half multiplications by 36? The beginner will say, four multiplications by 36, followed by a multiplication by 18; but this mode of defining breaks down immediately, for the two half operations would make more than the whole: two successive multiplications by 18 are equivalent to more than a multiplication by 36. It is multiplication by 6 which is the *half operation* to multiplication by 36. It is true that we do not apply the phrase *fraction of an operation* in our descriptive language; but we apply the symbol in our symbols. For just as every a^1 in a^n denotes one multiplication by a, every $a^{\frac{1}{2}}$ denotes that multiplication which twice repeated is equivalent to one multiplication by a. In like manner $a^{\frac{3}{7}}$ is the multiplier which being used 7 times, gives the same result as a used 3 times. We are not going to give the theory of simple powers, but only to put it in connection with what follows; and the reader will do well to observe, that in the very first ideas of ratios [ADDITION OF RATIOS] the notion of numerical quantity entering as a multiplier in repeated operations was so much in the minds of those who framed Euclid's language, that they spoke of what were really multiplications as if they had been additions. The same thing may be traced in calling 100 to 1 the duplicate ratio of that of 10 to 1 [RATIO], and 10 to 1 the subduplicate ratio of that of 100 to 1: duplicate means double, and subduplicate means half. The beginner must learn to understand numbers with reference to their force as indices of operation, and even the advanced student may require more study of this part of the subject than he suspects himself wanting.

Again, to establish the equation $\phi(x, m)=x^m$ when m is an integer, is not the same thing as establishing

$$\phi\left(x, \frac{m}{n}\right)=\sqrt[n]{x^m}:$$

in fact the symbol $x^{\frac{m}{n}}$ in algebra is well known [ROOT.] to be in its complete meaning

$$\sqrt[n]{x^m}\left\{\cos\frac{m}{n}.2k\pi+\sqrt{-1}\sin\frac{m}{n}.2k\pi\right\}$$

where k is any integer.

Next after the operations of powers and roots, nothing occurs more frequently in mathematical formulæ than successions of multiplications in which the multiplier is not always the same, as $1 . 2 . 3 \ldots . n$, $a(a+b)(a+2b) \ldots . (a+\overline{n-1}b)$. The various hints which had been given of the interpolation of fractional meanings, such as that of Wallis, and others of Leibnitz, the Bernouillis, Stirling, &c., have been extended with great power by the French and German mathematicians of the last eighty years. Two different lines were taken in the two countries. The Germans first began to consider how the ordinary notation might be extended. Vandermonde proposed to denote $m(m-1)(m-2) \ldots .$ to n factors by $[m]^n$; the brackets distinguishing it from m^n in the usual sense. Hindenburg, followed by Kramp and most of the Germans, proposed a much better notation. Considering x^m as denoting m unaltered factors, they made room in the symbol for a part expressive of the permanence of the factor, and wrote it $x^{m|0}$. Thus it became a particular case of $x^{m|a}$, which was made to stand for m factors, the first of which is x, and which alter by a at every step; giving

$$x^{m|a}=x(x+a)(x+2a) \ldots\ldots (x+\overline{m-1}a)$$

$$x^{m|-a}=x(x-a)(x-2a) \ldots\ldots (x-\overline{m-1}a)$$

$$(x+\overline{m-1}a)^{m|-a}=x^{m|a}$$

$$1^{n|1}=1 . 2 . 3 \ldots\ldots n=n^{n|-1},$$

and so on. This notation certainly opens the road to convenient expression of a large number of striking formulæ: take its binomial theorem for instance,

$$(x+y)^{n|a}=x^{n|a}+nx^{n-1|a}y^{1|a}+n\frac{n-1}{2}x^{n-2|a}y^{2|a}+\ldots$$

which is perfectly analogous to the ordinary theorem.

Also the following:—

$$(1+\mathrm{A}^{1|a}x+\mathrm{A}^{2|a}\frac{x^2}{2}+\mathrm{A}^{3|a}\frac{x^3}{2.3}+\ldots)^m=$$

$$1+(m\mathrm{A})^{1|a}x+(m\mathrm{A})^{2|a}\frac{x^2}{2}+(m\mathrm{A})^{3|a}\frac{x^3}{2.3}+\ldots\ldots$$

which is true for all values of m, and gives the binomial theorem if $\mathrm{A}=1$, $a=-1$, and the exponential theorem if $\mathrm{A}x=1$, $a=0$. The analogous theorem to Taylor's is

$$\phi(x+h)=\phi x+\frac{\Delta\phi x}{\Delta x}h^{1|-\Delta x}+\frac{\Delta^2\phi x}{\Delta x^2}\frac{h^{2|-\Delta x}}{1.2}+\ldots .$$

which is well known.

We think it is to be regretted that this notation has not been more adopted in England: we do not remember at this moment any writer who has made much use of it, except Mr. Peter Nicholson, in his works on Involution and on Increments.

A name was to be found for this extension. The notion of calling x^2, x^3, x^4, &c. the *powers* of x, was an extension of the term as used by Euclid, which applied to the square on a line only. Not that the square on a line was originally called its power, but that the power of a line was measured by the capacity of its square. The object of the old geometers was to reduce every area to a square, which enabled them to describe it by one line; and hence a line seems to have been considered as having more or less power (of inclosing space) according as its square was greater or less: the power being measured by the magnitude of the square. The phraseology seems to have reached those who were not geometers: thus Diogenes Laertius tells us that Pythagoras discovered that * the 'subtending side of a right-angled triangle is as powerful as the two containing sides together.' But those who will smile at the idea of the power of a line residing in its square, will laugh outright at the notion of Kramp, who proposed, seeing x^a represents the *powers* of x, that the symbol $x^{a|a}$ should represent its *numerical faculties* (facultés numériques). From the powers and the faculties we might have reached, possibly, the feelings and opinions, had it not been for Arbogast, who proposed to call the different cases of $x^{a|a}$ by the name of *factorials*, a term which has now gained considerable currency among the German writers, and was approved by Kramp himself.

The French, on the other hand, follow Euler and Legendre in connecting the factorials from the outset with definite integrals, and the latter in adopting a specific notation, not derived from that of powers. Legendre signifies $1 . 2 . 3 \ldots . n$ by $\Gamma(n+1)$, and hence the name of *gamma-functions* has been applied to them: they are best called *factorial functions*.

We shall give a slight account of the subject so far as it is in the way to be speedily reckoned among the elementary parts of mathematics.

A series or a product of n terms is only distinctly conceivable when n is integer, but if it can be represented by a function in which n enters as a usual symbol of magnitude, and not as a number of terms or operations, then the function is intelligible, though not the representative of the series, when n is a fraction. To take a very simple case: it would be absurd to demand the value of $1+2+3+\ldots\ldots+(n-1)+n$, when n is a fraction; but this series is $\frac{1}{2}n(n+1)$, which is always intelligible.

The equation

$$1+2+3+\ldots\ldots+n=\tfrac{1}{2}n(n+1)$$

is absurd except when n is a positive integer. In the times when the phrase 'less than nothing' was invented, it would have been said boldly that $2\frac{1}{2}$ terms of this series are $\frac{1}{2}\times 2\frac{1}{2}\times 3\frac{1}{2}$, or $35\div 8$, and that -7 terms of it are $\frac{1}{2}(-7)(-6)$ or 21. All that we should now say is that the function which, when n is integer, is equal to $1+\ldots\ldots+n$ becomes $35\div 8$, and 21, when n is $2\frac{1}{2}$ and -7. Whether we are likely to be the gainers by refusing extensions of language which naturally present themselves, remains to be seen: it seems to us that '-7 terms of the series $1+2+\ldots+n$' is a very innocent abbreviation of 'the value, when $n=-7$, of the function which, when n is a positive integer, is always equal to $1+2+\ldots+n$.' But at any rate, mathematicians are now in the habit of passing from expressions in which n is an index of number of operations, to the equivalents in which n is only an index of magnitude, and of using the latter in the most general sense.

But there is an infinite number of ways of representing, for example, a function which is $1+2+\ldots .+n$ when n is an integer. If ϕn be a function which is unity whenever n is an integer, such as $\cos 2\pi n$, $1+\sin 2\pi n$, &c., then $\frac{1}{2}n(n+1)\times\phi n$ answers the condition as well as $\frac{1}{2}n(n+1)$. It is usual however to start with a radical function which is free from periodic multipliers, and there is generally no difficulty in deciding upon the selection. In all the cases which are most useful, the radical function is the one which is clear of all sines and cosines.

But it is to be remembered that in this branch of the subject we have not advanced so far as to make it coextensive with the theory of powers: it is in fact precisely in the condition of the theory of powers before the discovery of the multiplicity of values in x^n when n is fractional. We are thus limited to an arithmetical view of the subject.

Some writers have censured Legendre for employing a new symbol $\Gamma(n+1)$, when $1^{n|1}$ was already in use: if, which may be doubtful, he had heard of the latter before he invented the former, he would, in our opinion, still have acted judiciously in inventing the additional symbol. He might have argued that it would not be wise to associate the second symbol with notions which are only true of the arithmetical case of it. As soon as the complete theory of the expression shall be given, $1^{n|1}$ is ready for it: in the mean while $\Gamma(n+1)$ expresses the arithmetical case of it, just as $\sqrt[n]{x^m}$ expresses that of $x^{\frac{m}{n}}$.

---

* We translate quite literally, to show that Laertius was not geometer enough to know that the subtending and containing was said of the *right angle*, not of the *triangle*. His words are ἴσον δύναται which Kraus, who in his turn was not geometer enough to venture the rendering of ὀρθογώνιον into Latin, translates *tantundem valere*. We take Laertius as meaning that the hypothenuse was as powerful as the two sides together: whether he understood his own phrase, or only caught it from the geometers, is another question. For othe uses of the same phrase, see IRRATIONAL.

The following are some of the cases which are strictly intelligible when n is an integer, and in which the radical function remains intelligible when n is fractional :—

$$1+\tfrac{1}{2}+\tfrac{1}{3}+\ \ldots\ +\tfrac{1}{n}=\int_0^1 \frac{1-v^n}{1-v}\,dv$$

$$1\times 2\times 3\ \ldots\ \times n=\int_0^\infty \epsilon^{-v}\,v^n\,dv$$

$$p\,(p+q)\ldots(p+\overline{n-1}\,q)=q^n\,\frac{\int_0^\infty \epsilon^{-v}\,v^{\lambda+n-1}\,dv}{\int_0^\infty \epsilon^{-v}\,v^{\lambda-1}\,dv}$$

where $\lambda=p\div q$.

The second equation, which may be thus written,

$$\Gamma\,(n)=\int_0^\infty \epsilon^{-v}\,v^{n-1}\,dv$$

is the most important. The following are its principal properties :

1. Γn is finite when n is positive, but is infinite when n is 0 or negative. This draws a great distinction between it and $1^{n|1}$; for the general formula which connects factorials of positive and negative exponents, with a common augment, is

$$x^{-n|a}\times(x-na)^{n|a}=1$$

Γn, which is infinite when $n=0$, diminishes from thence very rapidly, becomes 1 when $n=1$, and thence further diminishes until $n=1{\cdot}461632\ldots$, when it is least, being then $\cdot 8856032\ldots$. From thence it begins to increase, being 1 again when $n=2$, 1.2 when $n=3$, 1.2.3 when $n=4$, and so on.

2. The equation $\Gamma(n+1)=n\Gamma n$, so obviously true when n is an integer, is always true ; giving also

$$\Gamma(n+1)=n\,(n-1)\ldots\ldots(n-m)\,\Gamma\,(n-m)$$

for every integer value of m. Hence a table of values which extends through one unit is sufficient : and the most convenient interval is that from $n=1$ to $n=2$. If, for instance, we wanted to calculate from such a table the value of $\Gamma\,(5\tfrac{1}{3})$ we should reduce it to $4\tfrac{1}{3}\times 3\tfrac{1}{3}\times 2\tfrac{1}{3}\times 1\tfrac{1}{3}\times\Gamma\,(1\tfrac{1}{3})$, and take $\Gamma(1\tfrac{1}{3})$ from the table. Similarly Γn, when n is less than unity, would be found from $\Gamma\,(1+n)\div n$. When n is very small, Γn is $1\div n$ nearly.

3. The labour of calculating the table is much lessened by the following equation :—

$$\Gamma n\times\Gamma(1-n)=\frac{\pi}{\sin n\pi}$$

which is true when n lies between 0 and 1. One very useful result of it is $\Gamma\tfrac{1}{2}=\sqrt{\pi}$.

4. There is a constant to be introduced, which we shall call γ, the importance of which may in time compete with that of π and ϵ. It is the limit of the expression $1+2^{-1}+3^{-1}+\ldots+x^{-1}-\log x$, as x is increased without limit : it is also the value of

$$\int_0^1\left\{\frac{1}{1-v}+\frac{1}{\log v}\right\}dv \text{ and of } -\int_0^\infty \epsilon^{-v}\log v\,dv\,;$$

its value is

$$\gamma=\cdot 57721566490153286060 65\ldots$$

5. If S_n represent $1^{-n}+2^{-n}+3^{-n}+\ldots\ldots$ ad infinitum (See SUMMATION, for some of the values ; also 'Differential Calculus,' 'Library of Useful Knowledge,' p. 554), the logarithm (Naperian) of Γx may be found in either of the following ways :—

$$\log\Gamma(1+x)=-\gamma x+\frac{1}{2}S_2x^2-\frac{1}{3}S_3x^3+\frac{1}{4}S_4x^4-\ldots\ldots$$

$$=\frac{1}{2}\log\left(\frac{\pi x}{\sin\pi x}\right)-\tfrac{1}{2}\log\left(\frac{1+x}{1-x}\right)$$

$$+(1-\gamma)x-\frac{1}{3}(S_3-1)x^3-\frac{1}{5}(S_5-1)x^5-\ldots$$

$$=\frac{1}{2}\log(2\pi)+\left(x+\frac{1}{2}\right)\log x$$

$$-x+\frac{1}{12x}-\frac{1}{360x^3}+\ldots$$

6. A table of the values of comm. log. $\Gamma(1+x)$ is given by Legendre for every thousandth of a unit from $x=\cdot 000$ to $x=\cdot 999$: an abridgment of this table, with means of completing it, is in the 'Diff. Calc.,' 'Library of Useful Knowledge,' p. 587. This function Γx is a fundamental mode of expression for the results of large classes of definite integrals. [INTEGRALS, DEFINITE.]

7. The function $\Gamma(n+1)$ is the value, or one of the values, of $1^{n|1}$, and we have

$$p^{n|q}=q^n\,1^{\frac{p}{q}+n-1|1}\div 1^{\frac{p}{q}-1|1}$$

$$=q^n\,\Gamma\left(\frac{p}{q}+n\right)\div\Gamma\left(\frac{p}{q}\right)$$

which holds whenever the second side is real and finite.

The student who desires to know more of the theory may consult Kramp's 'Analyse des Réfractions Astronomiques,' Strasburg, 1799, 4to., and the article 'Factorielles,' in the Supplemental (or third) volume of Montferrier's 'Dictionnaire des Sciences Mathématiques,' Paris, 1840, 4to. Also the article 'Facultat' in Grunert's Supplement to Klügel's 'Worterbuch der Reinen Mathematik,' Leipzig, 1836, 2 vols. 8vo. On the form Γx see Legendre's well known works, the 'Exercices du Calcul Integral,' and that on Elliptic Functions. Some of the substance of these is in the treatise on the 'Differential Calculus', in the 'Library of Useful Knowledge.'

FACTORIES; FACTORY-SYSTEM. The word factory has had two different meanings. It formerly meant an establishment of merchants and factors resident in foreign countries, who were governed by certain regulations adopted for their mutual support and assistance against the undue encroachments or interference of the government of the countries in which they resided. In modern times these factories have, in a great measure, ceased to exist; because of the greater degree of security which merchants feel as regards both the justice of those governments and the protection, when needed, of their own country. The Venetians, Genoese, Portuguese, Dutch, French, and English have all had establishments in the nature of factories. In China the Portuguese established a factory at Macao, and the English at Canton. In most instances factories have at first obtained the privilege of trading, and afterwards procured for the precinct assigned to them some exemption from the jurisdiction of the native courts. In this state of things the supreme government of the country whose subjects have established the factory prepare laws for its control and administration, and treat it in fact as if it were its dependency, though the sovereignty of the native government is undisputed.

But in its usual acceptation, the word factory has now a different meaning. Modern legislation has declared that a factory means any building wherein steam, water, or other mechanical power is used to work any machinery employed in the manufacture of cotton, wool, hair, silk, flax, hemp, jute, or tow.

What is called the Factory System owes its origin to the inventions and skill of Arkwright; and it is probable that but for the invention of spinning machinery, and the consequent necessary aggregation of large numbers of workmen in cotton-mills, the name would never have been thus applied. It is in these mills that the factory system has been brought to its highest state of perfection. The power of subdivision of employment according to strength and skill, and that of bringing to bear upon every distinct process exactly as much force as is necessary, without waste, are the two great and valuable advantages of the factory system. The cotton-mills, and some of the circumstances connected with them, are noticed under COTTON MANUFACTURE.

The legislature has interfered to prevent children in factories from being tasked beyond their strength, to the permanent injury of their constitutions. This abuse was the more to be apprehended, because a large proportion of the children engaged in cotton-spinning are not directly employed by the masters, but are under the control of the spinners—a highly paid class of workmen, whose earnings greatly depend upon the length of time during which they can keep their young assistants at work. A parliamentary committee sat for the investigation of this subject in 1832, and subsequently a commission was issued by the crown for ascertaining, by examinations at the factories themselves, the kind and degree of abuses that prevailed, and for suggesting the proper remedies. In consequence of these inquiries, an act was passed in 1833 for regulating factories. Attempts had been made in 1802, 1816, and 1831, to legislate for the protection of factory workers; but only on a small scale.

The Act of 1833 (3 & 4 Will. IV. c. 103) contains numerous details; but the chief matters that relate to the subject are the following:—1. After January 1, 1834, no person under 18 years of age shall be allowed to work in the night, that is, between a quarter past eight P.M. and half-past five A.M., in any cotton or other factory in which steam or water, or any other mechanical power, is used to propel the machinery, except in lace factories. 2. No person under 18 shall be employed more than 12 hours in one day, nor more than 69 in one week. 3. There shall be allowed in the course of every day not less than 1½ hours for meals to every person restricted to the performance of 12 hours' work. 4. After January 1, 1834, no child shall be employed under 9 years of age, except in silk-mills. 5. After March 1, 1834, no child, except in silk-mills, shall be employed in any factory more than 48 hours in any one week, nor more than 9 hours in any day, who shall not be 11 years old; nor after March 1, 1835, who shall not be 12 years old; nor after March 1, 1836, who shall not be 13 years old; and these hours of work shall not be exceeded, even if the child has worked during the day in more factories than one. 6. Children and young persons, whose hours of work are regulated, shall be entitled to two holidays and eight half-holidays in the year. 7. Children, whose hours of work are restricted to 9 hours a day, are not to be employed without obtaining a certificate from a physician or surgeon, certifying that they are of the ordinary strength and appearance of children of the ages before mentioned, which certificate is to be countersigned by some inspector or justice. 8. The crown is to appoint, during pleasure, four persons to be inspectors of factories, with extensive powers as magistrates, to examine the children employed in the factories, and to inquire respecting their condition, employment, and education; and one of the secretaries of state shall have power, on the application of an inspector, to appoint superintendents to assist in carrying out the provisions of the act. 9. The inspectors are to make all rules necessary for the execution of the act, and to enforce the attendance at school, for at least two hours daily out of six days in the week, of children employed in factories; from whose weekly wages a deduction, not exceeding a penny in every shilling, is to be made for the expense of schooling. 10. No child shall be employed who shall not, on Monday of every week, give to the factory master a certificate of his or her attendance at school for the previous week. 11. The interior walls of every factory shall be whitewashed every year. 12. A copy or abstract of the act shall be hung up in a conspicuous part of every factory. 13. The inspectors shall regularly, once a year, report their proceedings to one of the secretaries of state. There are other clauses regulating the hours of working in mills where the use of water-power instead of steam-power disturbs the uniformity of the working; the steps to be taken in order to obtain regular certificates of age for the children requiring them; the erection of schools, where necessary; and the mode of enforcing the provisions of the act.

In the following year a short explanatory act was passed, to render more clear the meaning of the legislature on certain points; but with this exception, no further change was made till 1844. Committees of the House of Commons sat in 1840 and in 1841, and bills were from time to time introduced by individual members; but the Act of 1833 remained the groundwork of all the proceedings in respect to factories. The Act itself was, as we have already stated, in great part the result of a commission which had been appointed in the early part of 1833, and which had collected information by means of district commissioners in all the factory districts. This local machinery formed a groundwork for the inspectorship afterwards established by the government when the act was obtained. Four inspectors were appointed, and the British Islands were mapped out into four great divisions; the cotton and woollen district of Yorkshire, Lancashire, and the immediate neighbourhood, forming the 1st; the eastern and southern counties of England the 2nd; some parts of the West of England, nearly the whole of Wales, and the southern half of Ireland, constituting the 3rd; the northern half of Ireland, the whole of Scotland, and the four northern counties of England, the 4th. Each district was placed under one inspector, who made arrangements for becoming personally acquainted with every factory in his district employed for textile manufactures. Surgeons were appointed to grant the certificates required for the children; a system of occasional supervision was established; the inspectors communicated with the chief mill-owners on any points of difficulty which occurred; and the schooling of the children was gradually entered upon. One great difficulty however was this, that many manufacturers, as a means of escaping from the provisions of the Act, gradually discharged the children who were within the specified ages, and employed others of an age to which the education and the working-hours clauses did not apply; and many young children were thrown out of employ in consequence.

The Act rendered imperative some sort of schooling for the factory children; but it did not lay down rules for its government. The arrangements accordingly became of a very crude and heterogeneous character. The factory children received their education from five different sorts of schools, *Sunday Schools, Dame and Private Schools, Factory Schools, Church of England Schools*, and *Dissenters' Schools.* The disposal of the children on Sundays was a matter which did not come under the control of the inspectors; but the four classes of week-day schools were those which affected the daily regulations of the factories. The dame-schools or private schools, kept by mistresses or masters for their own profit, and not under the control or management of any other person, were of a very mean and inefficient kind, utterly wanting, in respect to instruction, books, and discipline, in the means of working out the required object. The factory-schools were such as were held in or near the factory where the children were employed, and were under the control and management of the owner of the factory. The Church Schools and the Dissenters' Schools, supported in many cases by powerful religious denominations, partook of the general character of such classes of schools, in respect to education and discipline. Many of the factory-schools, where the owner cared very little about the matter, were as bad as the dame-schools; whereas, in some cases the mill-owners took great interest and expended considerable sums in giving efficiency to the schools. At Messrs. Marshall's, at Leeds, for instance, a neat building was erected purposely as a school-room for the factory children, admirably fitted with every requisite for a large school.

In 1844 an Act was passed (7 & 8 Vict. c. 15) which came into operation in October of the same year, and effected certain changes in the law as to factories. An Office of Factory Inspectors was established in London. Persons beginning to occupy a factory were required to send notice of it to this office. The powers of inspectors to enter factories and schools are increased. The certifying surgeons are to be appointed by the inspectors; and the certificates are to have a definite form and expression. The whitewashing or painting of a factory is placed under strict regulations. Provision is made for the protection of children from the effects of the water in wet-flax spinning, and from accidents by the machinery while in motion. Children may be admitted and employed at eight years of age (the former minimum having been nine years). The maximum amount of daily work for each child is seven hours, subject to diminution in certain cases. All females are regarded in the same light as "young persons" (that is, persons from thirteen to eighteen years of age), as to the limitation of the hours of work. The recovery of lost time by the stoppage of machinery, the regulation of the meal-times in the factories, the holidays given to the children, the control of their attendance at school, the inspection of dangerous machinery, and many other points, are modified or extended in this Act; which however preserves the general character of the Act of 1833.

Before touching on the legislation of later years, we will present a few statistics of factories. The number of power-looms employed is to a certain degree, an index to the extent of factory operations; since the substitution of a power-loom for a hand-loom involves the substitution of a large and well-organised factory for, perhaps, the humble cottage of the hand-loom weaver. In a return made to government in 1836, the number of power-looms then employed is stated to have been about 92,000. There was another return concerning the number of factories, and of the persons working therein, in the same year; this gave about 304,000 persons in about 2860 mills, or 106 to each. By the commencement of 1839 the numbers had thus risen:—420,000 persons in about 4200 mills, or 100 to each. A return for 1843 gives a series of numbers under three different points of view; the first being according to the kind of textile material; the second, according to the location in different parts of the empire; and the third, according to the ages and sexes of the workpeople.

	No. of Factories.	Horse-power employed.	Persons employed.
Cotton . .	1,819	65,785½	259,385
Wool . . .	1,738	15,564½	86,446
Silk . . .	268	2,977	34,318
Flax . . .	392	9,585	43,487
Total . .	4,217	93,912	423,636
England . . .	3,475	77,804½	347,007
Scotland . .	492	12,448½	59,313
Ireland . . .	95	3,001	14,870
Wales . . .	155	657½	2,446
Total . . .	4,217	93,911½	423,636
Males under 21			100,654
Males 21 and above			77,999
Females under 21			163,252
Females 21 and above			81,566
Total			423,471

It may be well to remark that these numbers relate to the workpeople actually employed within the factories at one or other of the above four kinds of textile manufacture. The whole number who earn a living by these trades, including those engaged in hand-loom weaving, stocking-making, calico-printing, dyeing, bleaching, &c., very greatly exceeds the above, and has been variously estimated by different writers.

In 1845, Mr. Horner, whose district was very nearly co-extensive with Lancashire, gave the following as the state of his district in that year:—

	Mills.	Workers under 18.	Workers 18 & above.	Power Looms.
Cotton mills . .	1,724	69,155	128,305	138,717
Woollen mills . .	241	5,456	6,485	3,237
Flax mills . .	71	2,255	3,336	..
Silk mills . . .	32	3,121	3,324	995
Total .	2,068	79,987	141,450	142,949

The great strength of the woollen and worsted trades lay in another district, concerning which similar returns were not made.

In September, 1848, the mills and works within the limits of the town of Manchester, subject to the factory laws, were as follow:—

	Mills.	Hands.
Cotton	96	26,809
Silk	8	2,850
Worsted	3	169
Small wares	17	1,752
Print works	4	1,172
Dye works	23	1,847

In 1850 a return was made to the House of Commons respecting factories, more detailed and instructive than any before prepared. We will give a few of the results, calculated to illustrate different aspects of the subject. First, in respect to different parts of the United Kingdom, we have,—

	Factories.	Spindles.	Power Looms.	Horse Power.	Children employed.	Total employed.
England and Wales . .	3,680	22,850,010	272,588	109,824	34,155	495,707
Scotland . .	550	2,256,463	23,811	19,861	929	78,688
Ireland . . .	91	532,503	2,517	4,532	38	21,687
Total	4,330	25,638,716	298,916	134,217	35,122	596,082

In this table, the *horse-power* includes both steam-engines and water-wheels employed in working the machinery in the factories; they are nearly in the ratio of four-fifths steam-power to one-fifth water-power. The term *children* is applied to those at and under 13 years of age; from 13 to 18 the term applied is *young persons*. Taking the whole of the United Kingdom in one entry, and regarding only the ages and sexes of the persons employed, we find the following numbers:—

	Males.	Females.		
Under 13 . .	19,400	15,722	=	35,122
13 to 18 . .	67,864	329,577	=	555,307
Above 18 . .	157,866			
Total . .	245,130	345,299	=	590,429

In respect to females, one entry includes *young persons* and *adults*, as the same laws now apply to both classes. Of 100 persons working in factories, 58 are females and 42 males. About 6 per cent. of the workers are under 13 years old. The next classification we shall notice is that which depends on the kind of operations carried on. There are four classes, as follows:—

Spinning factories	2636
Weaving factories	454
Spinning and weaving factories	1005
Not specified	505
	4600

The five principal kinds of materials employed in the factories, and the persons employed in them, are distributed as follows:—

		Persons.
Cotton factories	1,932	330,924
Woollen factories	1,497	74,443
Worsted factories	501	79,737
Flax factories	393	68,434
Silk factories	277	42,544
	4,600	596,082

The number of factories here given (4600) is in excess of that given in the first table (4330); this probably arose from some of the factories being entered twice, in cases where they worked *mixed fabrics* of cotton and woollen, or cotton and silk, or woollen and silk. It is proper also to bear in mind that there are a few other discrepancies in the figures for different years, not explained in the returns from which they are taken. The cotton factories were rather less than half the whole number, but employed more than half the entire number of operatives. The average number of operatives in cotton factories was 120; the average in all factories was 75. Out of the 1932 cotton factories, no less than 1235 were in Lancashire; out of the 1998 woollen and worsted factories, no less than 1298 were in Yorkshire. It will be seen that a remarkable parallelism exists in these numbers; 64 per cent. of all the cotton factories were in Lancashire, and 65 per cent. of all the woollen and worsted factories were in Yorkshire.

The factory legislation since 1844 has comprised five statutes. In 1846 a new Act came into operation, which brought calico-printing works within the range of the inspectors. By the terms of another Act, passed in 1847, the *children* and *young persons* are to work not more than eleven hours a day from July 1, 1847, and not more than ten hours after the 1st of May, 1848. The same provisions were made in relation to women of whatever age; and it thus arose that all women, boys, and girls employed in factories were limited in their hours of working, adult males being alone excepted. Another Act, passed in 1850, introduced a few minor changes, chiefly with a view to prevent night-work in factories. In 1853 an Act was passed making further regulations touching the employment of young children in the evening or night. It was enacted that, after the 1st of September in that year, children should not begin work before six in the morning, or remain at work after six in the evening; in the winter months the hours might be from seven till seven, on due notice being given to the sub-inspectors; work to end on Saturdays at two o'clock. These regulations, subject to exceptions under special circumstances, were to be incorporated with such of the provisions of previous statutes as were not repealed or modified by them. In 1856 an Act was passed to remove doubts concerning the statute of 1844 in reference to mill-gearing; the mill-owners had interpreted this statute in one sense, the inspectors in another; and thereupon the new Act declared that the mill-fencing should only apply to such parts of the machinery as children, young persons, and women are liable to be injured by, either in passing or in their ordinary occupations in the factory. Very violent accusations and recriminations had arisen on this subject, and the statute was intended to settle the question.

It will be seen, on reference to the articles BLEACHING and CALICO-PRINTING, that strenuous efforts have been made to bring bleach-works and dye works under the same regulations as spinning and weaving factories and print works. Much inquiry by commissioners, and much debating in parliament, were bestowed upon this subject in the periods between 1854 and 1857. For a brief statement of the results we refer to the articles above named. There was also, about the year 1857, a strenuous effort made by some of the factory operatives and their advocates in parliament to obtain a "ten hours' bill," but without success.

Having in former paragraphs given a few statistics of factories at various dates since the commencement of factory legislation, we here give a few more relating to 1856, the last year concerning which any very exact enumeration has been made; for, it may be remarked, the half-yearly reports of the inspectors usually advert to current events, and not to total results. The five kinds of factories for textile goods (cotton, woollen, worsted, flax, and silk) were all examined, throughout every part of the United Kingdom, and certain particulars were noted down concerning all. These particulars, and the figures relating to them, we will present in a more condensed form, sufficient for the present purpose:—

	Factories.	Spindles.	Power Looms.	Horse Power.	Males Employed.	Females Employed.	Total Employed.
Cotton . . .	2,210	28,010,217	298,847	97,132	157,186	222,027	379,213
Woollen . .	1,505	1,786,972	14,453	25,901	45,588	33,503	79,091
Worsted . .	525	1,324,549	38,956	14,904	30,023	57,771	87,794
Flax . .	417	1,288,043	7,689	18,322	23,446	56,816	80,262
Silk . . .	460	1,093,799	9,260	5,176	16,899	39,238	56,137
Total	5,117	33,503,580	369,205	161,435	273,137	409,360	682,497

In reference to the several parts of the United Kingdom, without noting any separation of the different textile manufactures, the figures stood thus:—

	Factories.	Spindles.	Power Looms.	Horse Power.	Males Employed.	Females Employed.	Total Employed.
England and Wales .	4,432	30,122,165	339,382	133,092	241,309	330,768	572,077
Scotland . .	530	2,643,049	26,485	19,706	21,279	56,153	77,432
Ireland . .	155	738,366	3,388	8,037	10,549	22,439	32,988

The largest items of course relate to the cotton manufacture in England and Wales. The figures are truly astonishing; 2,050 factories, 26,000,000 spindles, 280,000 power looms, 86,000 horse-power for moving machinery, 14,000 males employed under 13, 134,000 over 13, 10,000 females under 13, and 180,000 over 13. In the interval between 1850 and 1856, the several items, as will be seen on comparison, varied very unequally among themselves. Taking four different years, and three classes of factory operatives, it has been found that the latter have changed somewhat in the relative percentage.

Years.		Males and Females under 13.		Males over 13.		Females over 13.		
1835	..	13	+	37	+	50	=	100
1838	..	6	+	39	+	55	=	100
1850	..	6	+	38	+	56	=	100
1856	..	7	+	36	+	57	=	100

This seems to show that women have increased in number in factories more rapidly than men, boys, or girls.

In the article EMBROIDERY AND SEWING MACHINES, it is mentioned that shirts, collars, and other kinds of ready made linen sold in London, are in a large degree sewn and stitched by machinery. We may here add a few words on this subject in relation to the north of Ireland, where the factory system has been brought into connection with it. The manufacturers of Manchester and Glasgow, and the wholesale dealers of those towns and of the metropolis, have found out that the Irish peasant girls work very neatly with the needle, and are eager to obtain employment on linen, cotton, or muslin work, whether by the ordinary plying of the needle, or by tambouring and sewing machines. Some of the firms now own large establishments in Ireland, where the factory system is in part carried out. In and near Londonderry alone there are more than a dozen factories in which sewing-machines are employed; these machines are at present about 700 in number; and the working of them, with subsidiary operations, employ 1800 women and girls. Taking one with another, these persons (mostly girls) earn about 6*s.* per week each on an average; some, who are quick and clever, occasionally earn as much as 20*s.* In one of the establishments the sewing-machines are driven by steam-power, and are fitted with patent self-acting regulators, still further to increase the automatic action. Besides these machine-sewers working in factories, there are 16,000 hand-sewers scattered over the counties of Londonderry, Donegal, Tyrone, Fermanagh, and Antrim.

We may remark, in conclusion, that in the United States, spinning and weaving factories are much more frequently owned by joint-stock companies than in England. The celebrated cotton factories at Lowell, and numerous others in the northern states of the Union, are held by companies; they are large, well provided with machinery, and worked by operatives who maintain a somewhat higher status than those of England. This may in part result from the more general diffusion of education in that country, a fact of which there seems to be no doubt. In these large American spinning and weaving mills, owned by companies, the proprietors often provide boarding-houses, in which many of the workpeople—especially girls and young women away from their parents' homes—are supplied with food and lodging under a well-organised system, and at prices calculated rather in relation to the well-being of the persons themselves than to the realisation of a profit.

FACULTIES. [UNIVERSITY.]

FAGINE. An alkaloid of unknown composition contained in the beech-nut, *Fagus sylvatica*.

FAGOT, SAP-, a small kind of FASCINE, about 3 feet in length.

FAINTING. [SYNCOPE.]

FAIR, an annual or fixed meeting of buyers and sellers; from the Latin *feria*, a holiday. Fairs in ancient times were chiefly held on holidays.

Anciently, before many flourishing towns were established, and the necessaries or ornaments of life, from the convenience of communication and the increase of provincial civility, could be procured in various places, goods and commodities of every kind were chiefly sold at fairs, to which, as to one universal mart, the people resorted periodically, and supplied most of their wants for the ensuing year. The display of merchandise and the conflux of customers at these the most comprehensive markets for domestic commerce was prodigious, and they were therefore often held on open and extensive plains. Warton, in his 'History of English Poetry,' has given a curious account of that of St. Giles's Hill or Down, near Winchester. It was instituted and given as a kind of revenue to the Bishop of Winchester by William the Conqueror, who by his charter permitted it to continue for three days; but in consequence of new royal grants, Henry III. prolonged its continuance to sixteen days. Its jurisdiction extended seven miles round, and comprehended even Southampton, then a capital trading town; and all merchants who sold wares within that circuit, unless at the fair, forfeited them to the bishop. As late as 1512, as we learn from the Northumberland Household-book, fairs still continued to be the principal marts for purchasing necessaries in large quantities, which are now supplied by the numerous trading towns.

Philip, king of France, complained in very strong terms to Edward II. in 1314 that the merchants of England had desisted from frequenting the fairs in his dominions with their wood and other goods, to the great loss of his subjects, and entreated him to persuade, and, if necessary, to compel them, to frequent the fairs of France as formerly, promising them all possible security and encouragement. (Rym., 'Fœd.,' tom. iii., p. 482.)

When a town or village had suffered from misfortune, by way of assisting to re-establish it, a fair, among other privileges, was sometimes granted. This was the case at Burley, in Rutlandshire, 49th Edw. III. ('Abbrev. Rot. Orig.,' vol. ii., p. 338.)

The Chronicles of Stow and Grafton, published in Queen Elizabeth's time, contain lists of the fairs of England according to the months.

No fair or market can be held but by a grant from the crown, or by prescription supposed to take its rise from some ancient grant, of which no record can be found.

The fairs of Frankfort-on-the-Mayn and Leipzig are still pre-eminent in Europe; each is held three times a year. Leipzig at these times is the mart and exchange of Central Europe, and is visited by merchants and foreigners from the most distant parts of the globe, sometimes to the number of thirty or forty thousand. The whole book-trade of Germany is centred in the Easter fair at Leipzig. Nishnei Novgorod, in Russia, at the confluence of the Oka and the Wolga, has a great annual fair in June, at which an immense number of traders assemble, many of them from the most remote parts of Asia.

FAIRIES, a small sort of imaginary spirits of both sexes in human shape, who are fabled to haunt houses in companies, to reward cleanliness, to dance and revel in meadows in the night-time, and to play a thousand freakish pranks. Both sexes are represented generally as clothed in green, and the traces of their tiny feet are supposed to remain visible on the grass for a long time after their dances: these are still called fairy-rings or circles. They are also fabled to be in the practice of stealing unbaptised infants and leaving their own progeny in their stead. Besides these terrestrial fairies, there was a species who dwelt in the mines, where they were often heard to imitate the actions of the workmen, to whom they were thought to be inclined to do service. In Wales this kind of fairies was called "knockers," and was said to point out the rich veins of silver and lead. Some fairies are fabled to have resided in wells. It was also believed that there was a sort of domestic fairies, called, from their sunburnt complexions, *Brownies*, who were extremely useful, and who performed all sorts of domestic drudgery. The words fairy and browny seem at once to point out their own etymologies.

Bourne, in his 'Antiquitates Vulgares,' supposes the superstition relating to fairies to have been conveyed down to us by tradition from the Lamiæ, or ancient sorceresses; others have deduced them from the lares of the Romans. Dr. Percy tells us, on the assurance of a learned friend in Wales, that the existence of fairies is alluded to by the most ancient British bards, among whom their commonest name was that of the Spirits of the Mountains. The most general conjecture, however, is, that these imaginary people are of Oriental origin, and that the notion of them was first entertained by the Persians and Arabs, whose traditions and stories abound with the adventures of these imaginary beings. The Persians called them *Peris;* the Arabs, *Ginn;* and the Arabs assigned them a peculiar country to inhabit, which they called *Ginnistan*, or Fairy-land.

Shakspere has been singularly happy in his dramatic exhibition of fairies. The belief in these fabled beings has still a fast hold upon the minds of many of our rustics, which may perhaps be considered as a remnant of that credulity which was once almost universal. Poole, in his 'English Parnassus,' has given the names of the fairy court, their clothing, and their diet. Dr. Grey, in his 'Notes on Shakspere,' gives us a description, from other writers, of fairy-land, a fairy entertainment, and fairy hunting; and Dr. King has given a description of Orpheus' fairy entertainment in his 'Orpheus and Eurydice' (edit. 1776, vol. iii., p. 212). Wieland in his 'Oberon' gives an account of the quarrel of Oberon and Titania, with consequences varying considerably from those detailed by Shakspere in his 'Midsummer Night's Dream.' A charm against fairies was *turning the cloak*. The reader who would look further into fairy mythology may consult Percy's 'Reliques of Antient English Poetry;' Sir Walter Scott's 'Essay on the Fairy Superstition,' in the 'Minstrelsy of the Scottish Border;' Keightley's 'Fairy Mythology,' published in 1828, in which the legends of different countries are collected; and Jacob Grimm's 'Deutsche Mythologie,' 1835.

FAITH (*fides*, in Latin), means belief or trust in a fact or doctrine, and is more especially used to express the belief of Christians in the tenets of their religion, and also by figure to mean that religion itself. The great divisions of Christianity, the Roman, the Greek, the Reformed or Calvinist, the Episcopal English, the Independents, and the Protestant or Lutheran churches, have each separate confessions of faith, but they all acknowledge the great fundamental points of the Christian faith or religion, namely, the inspiration of the Scriptures, and the divinity of Jesus Christ. [CONFESSIONS.] In the earlier ages of the Church the chief controversies of theologians, especially in the East, ran upon metaphysical questions concerning the mysteries of the Trinity, the Incarnation, and the divine nature of the Saviour. In modern times controversy has run more frequently upon moral questions concerning the conduct of men, the requisites of salvation, and the discipline of the Church. Faith, the necessity of which is acknowledged by all Christians, has been viewed in various lights with respect to its efficacy. From the earliest ages the Church has taught that faith, or belief in the Redeemer, joined with good works, was necessary for the justification of man; that good works, that is, works acceptable to God, could only be produced by the Spirit of God influencing the heart, but that the human will must co-operate with grace in producing them, though the human will alone is powerless to good unless assisted by divine grace. Still, man being a free agent, the will can call on God, through the merits of the Saviour, for a measure of his grace to assist its own efforts. Thus the co-operation of God and man was held as the means of the justification and salvation of the latter. Luther, however, and Calvin, denied the power of the will to call on God for his grace; they substituted faith, and faith alone, in the merits of the Redeemer, as the means of salvation, by which faith man firmly believes that his sins are at once remitted. But this faith must be sincere, absolute, without a shadow of doubt or distrust; and as man cannot of himself obtain this, it can only be given to him by inspiration of the Spirit of God. Here the question of faith becomes involved with those of grace and predestination. As for our works, both Luther and Calvin look upon them as absolutely worthless for our salvation. Some fanatics, and the Anabaptists among the rest, drew from these premises of the leading reformers some very dangerous consequences, which Luther and Calvin had not anticipated, such as that men might live as profligately as they pleased, and yet, by the inspiration of divine grace, might obtain the faith requisite for their salvation.

The opinions of Luther and Calvin on the subject of faith and predestination have been since considerably modified by many Protestant divines, who have admitted that the will of man must co-operate in order to obtain the grace necessary for justification. The Roman Catholic church admits the merit of good works and repentance, united with faith, for the purpose of salvation. But then, it requires an absolute faith in all the decisions of its general councils in matters of dogma, without the least liberty of investigation on the part of the laity, and without any doubt, for doubt itself is held to be sinful. The Reformed and Protestant churches, generally speaking, hold faith in the fundamental dogmas of Christianity as an essential requisite for salvation.

FAKI'R, an Arabic word, meaning "poor," which is applied to the ascetics of several parts of the eastern world. In this sense it is synonymous with the Persian and Turkish dervish. The word fakir is chiefly used in India. There are fakirs who live in communities like the monks of the western world, and others who live singly as hermits, or wander about exhibiting strange displays of self-penance and mortification. Many of them are considered as hypocrites, and others are fanatics or idiots. [Dervish.]

FALCONRY, or **HAWKING**, the art of training and flying hawks to take other birds. Julius Firmicus, who lived in the middle of the 4th century, is the first Latin writer who speaks of falconers and the art of teaching one species of bird to fly at and catch another. The art, however, had been, in all probability, practised in the East from remote ages, whence it certainly came to Europe.

From the Heptarchy to the time of Charles II. falconry was a principal amusement of our ancestors in England: a person of rank scarcely stirred out without a hawk upon his hand, which, in old illuminations and upon ancient seals, is the criterion of nobility. Harold, afterwards king of England, is thus represented in the Bayeux tapestry, when visiting the court of William, duke of Normandy.

In 'Domesday Book' the practice of falconry is illustrated by numerous entries. In several places we find a sum, no less than ten pounds, made the optional payment instead of finding a hawk ('Domesd.,' tom. i., fol. 134, b. 172, 230); and once, at Worcester (tom. i. 172) a Norway hawk is specified. Aeries, or places destined for the breeding or training of hawks, are entered in the Survey in Buckinghamshire, Gloucestershire, Worcestershire, Herefordshire, Shropshire, and, more frequently than in other counties, in Cheshire, as well as among the lands between the Ribble and the Mersey.

Nor were hawks less prized at subsequent periods. According to Madox ('Hist. Excheq.,' i. 273), in the 14th Hen. II., Walter Cnot, one of the king's tenants, rendered his rent at the exchequer in three hawks and three girfalcons. King John had also his hawks (Pat. 4, Joh. m. 2); and upon the Patent Roll of the 34th Hen. III. a copy occurs of the letter which the king sent in that year to the king of Norway for hawks. In the 34th Edw. III. it was made felony to steal a hawk; to take its eggs, even in a person's own ground, was punishable with imprisonment for a year and a day, besides a fine at the king's pleasure. In Queen Elizabeth's reign the imprisonment was reduced to three months: but the offender was to find security for his good behaviour for seven years, or lie in prison till he did. (Pennant, 'Brit. Zool.,' 8vo, Lond., 1812, vol. i., p. 212.)

By an entry upon the Originalia Rolls of the 35th Edw. III. ('Origin.,' vol. ii., p. 267) it appears that a falcon gentil cost 20*s.*, a tersel gentil 10*s.*, a tersil lest our 6*s.* 8*d.*, and a lanner 6*s.* 8*d.*: these were the prices which the sheriff was to give for hawks for the king's use. In an account-book of the 20th Hen. VIII. a goshawk and two falcons are prized at 3*l.*, and five falcons and a tersil at 8*l.* Bert, in his Address to the Reader, prefixed to his 'Treatise of Hawkes and Hawking,' published in 1619, says he "had for a goshawke and a tarsell a hundred marks."

Falconry was attempted to be revived by George, earl of Orford, who died in 1791; and in Yorkshire, Col. Thornton had a hawking establishment at a rather later period. Sir John Sebright and a few other gentlemen also practised it in Norfolk at the beginning of the present century. As a rural diversion, however, principally in consequence of the enclosures, it has gone into disuse, though there are still occasional attempts made for its revival.

A list of the hawks which were most used by sportsmen in the time of Charles I. is given in Walton's 'Complete Angler;' and an explanation of the words of art in hawking will be found in Latham's 'Falconry,' 4to, Lond., 1633.

The earliest printed treatise on hawking in English is the 'Book of St. Alban's,' fol., 1481, ascribed to Juliana Barnes or Berners, abbess of Sopwell. [Berners, Juliana, in Biog. Div.] There are numerous other and curious treatises upon falconry both in French and English, some of them of very rare occurrence. 'Le Miroir de Phebus, avec l'Art de Fauconnerie,' published at Paris in 8vo, without date, was the first work upon the subject printed in the French language.

FALL OF BODIES. Under this head we propose simply to explain the laws which regulate the fall of a material substance, supposed either to be allowed to drop or to be projected directly upwards or downwards. The motion of a body projected in an oblique or horizontal direction comes under Projectiles, Theory of; the nature of the forces which cause the descent or retard the ascent, under Accelerated Motion, Accelerating Force, Acceleration, Attwood's Machine, Gravity, &c.; and the circumstances which influence more or less the results about to be specified, under Projectiles, Resistance, Motion of the Earth, Motion, Laws of.

The resistance of the air does not greatly affect the motion of bodies, unless either—1, the bodies themselves be very light, as in the case of feathers, or, 2, the velocities be very great, as in that of a cannon ball. The law according to which this resistance acts is not well ascertained for great velocities, but for moderate velocities it is not far from the truth to say that it is as the square of the velocity; that is to say, whatever resistance there may be to a velocity of 10 feet per second, there is *four* times as much to 20 feet per second, *nine* times as much to 30 feet per second, and so on.

Neglecting the resistance of the air, let us first suppose a body (say a bullet) to be allowed to drop from a height above the earth. The law of its motion is as follows. It acquires velocity uniformly at the rate of $32\frac{1}{6}$ feet per second; that is, at the end of a quarter of a second it is in such motion as would, were the action of the earth to cease, cause it to describe $8\frac{1}{24}$ feet in a second. At the end of one second the rate of motion is $32\frac{1}{6}$ feet per second; at the end of two seconds, $64\frac{1}{3}$ per second, and so on; that is, the fall of a body is a uniformly Accelerated Motion. In the article just cited the law of this motion is further explained. We shall here collect the principal formulæ connected with the subject, referring to Pendulum and Attwood's Machine for the manner in which the main fact of the acceleration being $32\frac{1}{6}$ feet per second is proved and verified.

Let $g=32\frac{1}{6}$

$t=$ the number of seconds during which the motion has lasted when the body has attained a velocity of v feet per second, and described a length of s feet.

First, suppose the bullet simply to drop without any initial impulse being communicated. Then

$$v=g\,t, \qquad s=\tfrac{1}{2}g\,t^2=\tfrac{1}{2}v\,t, \qquad v^2=2\,g\,s.$$

Thus, either of the three, v, t, s, being given, the others may be found.

Secondly, suppose the bullet to be projected downwards with a velocity of a feet per second: the consequence is still a uniform addition of g feet per second to the velocity, and we have

$$v=a+g\,t, \qquad s=a\,t+\tfrac{1}{2}g\,t^2, \qquad v^2-a^2=2\,g\,s.$$

Thirdly, suppose the bullet to be projected upwards with a velocity of a feet per second. The action of the earth begins by producing a loss of velocity at the rate of $32\frac{1}{6}$ feet lost per second. This lasts until the velocity of the bullet is entirely destroyed, after which it begins to descend without any initial impulse, and we have the first case repeated.

During the ascent

$$v=a-g\,t, \qquad s=a\,t-\tfrac{1}{2}g\,t^2, \qquad a^2-v^2=2\,g\,s,$$

and the height through which the bullet will ascend is $a^2\div 2\,g$ feet, the time of doing which is $a\div g$ seconds. After this the first case may be repeated; but this is not necessary, for the preceding equations will continue to represent the relations which actually exist, provided that v, becoming negative, be interpreted as indicating that the turn has taken place and the bullet has begun its descent, and also that s becoming negative be interpreted to mean that the descent has continued until the bullet has passed through the point from which it was first thrown, and fallen below it. For instance (supposing $g=32$ for simplicity), let a bullet be projected *upwards* with a velocity of 100 feet per second, where will it be, and at what rate will it be moving, at the end of ten seconds?

$v=100-32\times 10=-220$, or the bullet is moving *downwards* at the rate of 220 feet per second.

$s=100\times 10-\frac{1}{2}\times 32\times 10^2=-600$, or the bullet is 600 feet below the point from which it was thrown upwards.

FALLACY, as defined by Archbishop Whately, is any unsound mode of arguing which appears to carry conviction and to be decisive of the question in hand, when in fairness it is not. Bentham's definition in his 'Book of Fallacies' is this: "By the name of fallacy it is common to designate any argument employed, or topic suggested, for the purpose, or with a probability, of producing the effect of deception—of causing some erroneous opinion to be entertained by any person to whose mind such argument may have been presented." Accordingly if an argument be undesignedly vicious, and without any attempt at deception, it is more correctly termed a paralogism, and it is the intention of fraud that constitutes the fallacy or sophism. There is, however, a legitimate use of fallacy which is too often unnoticed by writers on logic. Thus, in modern times Kant has employed the dilemma for a purely scientific purpose; and from the impossibility of two opposite and conflicting cases, has inferred, not as is the usual deduction, that the hypothesis upon which they both rest is false and untenable, but that the truth is intermediate. In like manner did Zeno of Elea infer the inadequacy of sense to represent the truth, from his conclusion that either a bushel of corn must make no noise in falling, or else the fall of the smallest portion of a single grain must be perceptible to the ear. Again, the famous 'Megarian fallacies of the Heap and the Bald head' (acervus calvus), in which it is proved that these notions are incapable of any precise determination, may have been designed to show that the distinctions of degree (here represented by Heap and Bald head) are unavailable for philosophical purposes, and thereby to call attention to the difficulty of admitting into science the vague representations of sense.

Aristotle, in his treatise 'De Sophisticis Elenchis,' has laboured to expose and classify the different fallacies which he terms *sophismata* (σοφίσματα). He divides them into those *extra dictionem* (ἔξω τῆς λέξεως), where the fallacy is in the process of reasoning, and those *in dictione* (παρὰ τὴν λέξιν) where it lies in the subject-matter. The former have by the schoolmen been called formal, the latter material. Dr. Whately proposes the terms logical and non logical; which terminology has at least the advantage in a scientific point of view that it excludes from the domain of logic much that is extraneous to it; for the fallacies of form may be reduced to the syllogism with four terms which the analytical process of demonstration can alone discover, whereas those of the matter must be corrected by the formation of valid principles and a correct generalisation of terms, which belong to the synthesis of induction, which is totally alien from logic as the science of demonstrative reasoning.

For an enumeration and exposition of the several sophisms, see the sections on fallacy in Whately's 'Logic;' and for the exposure of that class of fallacies which he has called political fallacies, the work of Bentham, already cited.

FALLING STARS. [AEROLITES.]

FALLOW operations are those acts of cultivation which depend for their fertilising influence rather on the mere tillage of the soil, its disintegration, disturbance, and exposure to external agencies, than on the direct addition of fertilising matter. Originally the term *fallow* applied to that portion of land in which no seed is sown for a whole year, in order that the soil may be left exposed to the influence of the atmosphere, the weeds destroyed by repeated ploughings and harrowings, and the fertility improved at a less expense of manure than it would be if a crop had been raised upon it. Even then a large portion of the benefit derived from fallow was attributed to the mere tillage operations included in the term; but, in addition to this, manuring was (and indeed still is) an almost invariable part of a summer fallow. A bare summer fallow is, however, now comparatively rare, and fallow crops, those which allow of fallow operations during their growth, are the fertilising agents substituted in its place.

The practice of fallowing land is as old as the Roman Empire. It appears that wherever the Romans extended their conquests and planted colonies, they introduced this mode of restoring land to a certain degree of fertility when exhausted by bearing grain. The principle on which it was recommended was, however, erroneous. It was thought that the land grew tired of raising vegetable produce and required rest, and hence this rest was often all that constituted the fallow; the tillage, which alone is the improving part of the process, being almost entirely neglected. Where land was abundant and the population thin, it was no great loss to allow a considerable portion of the soil to remain unproductive; and it was cheaper to let land lie fallow during the course of a whole year, which gave ample leisure for every operation, than to accelerate the tillage and increase the manure put upon it. But when land becomes of greater value with the increase of population, it is a serious loss if a great portion of the soil be thus left in an unproductive state. Accordingly the attention of agriculturists has been turned to lessen the necessity of fallows, and to substitute some other means of restoring fertility. It is acknowledged by all experienced farmers that manure alone is not sufficient for this purpose. The ground must be tilled and noxious weeds destroyed; and the only efficacious mode of doing so is to stir the ground at the time when their seeds have vegetated, their roots have made shoots, and before any new seed can ripen. But this is exactly the time when corn is usually growing, and when the land cannot be stirred to expose it to the heat of the sun and to dry the roots which are turned up. The only apparent remedy is therefore not to sow it during one summer, and on this principle lands are usually fallowed. The manner in which this is done has been noticed before [ARABLE LAND]; and the common process is so simple, that, provided the purpose of fallowing be kept in view, the operations require only a little attention to time and weather to be performed aright.

There is no difference of opinion respecting the manner of extirpating weeds by repeated ploughing and harrowing, but there is with respect to the influence of the heat of the sun upon the land. Some men are of opinion that light is the great purifier of the soil; that it decomposes certain noxious particles, which are the result of the formation of the seed, and which have been termed the excrements of plants. Physiologists agree that the roots draw the nutritive juices out of the soil, that they undergo a chemical change in the plant, and that there is an exudation also from the roots, which may be looked upon as the residuum of the natural process. De Candolle, Raspail, and other eminent physiologists have placed this point beyond controversy; but no one has yet been able to collect these matters so as to analyse and compare them; and the reasonings on the subject have been merely conjectural. In particular soils and situations a scorching sun has a pernicious effect on the soil which is exposed to his rays; and where it is shaded by a crop which covers it completely, it seems to have acquired fertility, which the exposed surface has not. But this is not sufficient to establish a general rule. Some soils which are of a wet nature are greatly improved by being as it were baked in a hot sun. Not only are the weeds destroyed by the abstraction of moisture, but the soil thus becomes lighter and more friable. On sandy soils the reverse is the case, and on intermediate loams the effect will be more or less advantageous as they approach nearer to the clay or to the sand. In light sandy soils, then, it is probable that the only advantage of a naked fallow is to kill weeds, especially the couch-grass (*Triticum repens*), which is apt to infest light soils: and that the exposure to the sun in hot weather is not only no advantage, but probably detrimental. If, then, any means can be devised of clearing light lands from weeds without leaving them fallow for a whole summer, a great advantage will be obtained. This has been effected completely by the cultivation of turnips and clover, which was first practised in the light soils of Flanders, and afterwards introduced into the similar soils of Norfolk, from whence it has spread all over Great Britain, and is beginning to be adopted more generally in Ireland. The advantage of the turnip culture is so great in light lands, that it has gradually been extended through the different gradations of loams, till it has reached even the colder and stiffer clays, on which it would at one time have been thought absurd to attempt to raise this root. But this has been attended with an important benefit. It has made the cultivators of heavy soils turn their attention to the drying of their lands, by draining, and to improving their texture by burning and by deep tillage, in order to make them capable of bearing turnips; and although the extended culture of this useful root is not what we should recommend for cold wet clays, we highly approve of all improvements which will make such lands capable of bearing good crops of turnips. Unless the turnips can be consumed by sheep on the spot, or by cattle near at hand, without injuring the land in taking off the turnips and carting on the manure, there will be no great advantage in a crop of turnips; and some other substitute must be found for the occasional fallow before it can be altogether abandoned. The great hope of the clay-land farmer, as to the possibility of the successful cultivation of a fallow crop on such land, rests on the mangold-wurzel and the cabbage crop [CABBAGE; MANGOLD, *Cultivation of*], which are especially fitted for soils of the stiffer class. On light lands the preparation for the turnips, the abundant manuring, and subsequent hoeing, are as effectual in cleaning the land and bringing it into a fertile state as any complete fallow could ever be; and the clover smothers and destroys the seed weeds which may have come up amongst the barley or oats sown after the turnips. There are several ways in which the cultivation of light soils may be varied without adhering strictly to the Norfolk rotation, so as to introduce a greater variety of produce. Tares may be sown on the better sorts of light lands after a good tillage given immediately after harvest. If they are fed off or cut green in May and June, early turnips may be sown after them, which will be fit to feed off or draw for the cows in September, in good time for ploughing up the land for wheat-sowing. In this case the land gets all the ploughing necessary to clean it completely, and exactly at the best time. Three ploughings may be given after the tares if the land is not clean, and the turnips being well hand-hoed and horse-hoed, the land will be perfectly clean to receive the wheat-seed. Manure may be put on for the tares or the turnips; and if these are fed off with sheep, they will so enrich the soil, that the next crop cannot fail to be abundant. As a general rule, however, tares are better adapted for the clay soils; and rye is a better crop to take before turnips on sandy loam. By varying the management of light land according to circumstances, and with some judgment, many more profitable crops can be raised than by the common simple rotation, in which a fourth of the land is sown with turnips. If this crop fails, which is often the case where it recurs so often, the whole system is deranged, and the loss is very great. The introduction of a greater variety of produce in the cultivation of light lands, in imitation of the Flemish practice, and the increase of stock kept in consequence, would be an important step in the improvement of British husbandry.

On heavy soils it is often impossible to keep the land clear of weeds, in wet climates and unfavourable seasons, without a complete fallow, and when this is the case it is best to do the thing effectually. Upon cold wet soils, which should always first of all be well under-drained, no pains should be spared to get the land perfectly clean: if both climate and circumstances interfere with the thorough cultivation of a fallow crop, then let the soil be exposed to the frost of two winters and the heat of one summer and part of another, as already mentioned [ARABLE LAND.] Only one crop is lost by this method, and if the land is properly worked, cleaned, and manured in autumn, it may be sown with barley or oats in the spring of the second year. The crop will be ample, and the subsequent produce of clover equally so, and the land so clean, that, with proper manuring, several crops may succeed, such as wheat, beans, oats, tares, wheat, without the necessity of another intervening fallow. The advice we would impress on the minds of the cultivators is—Avoid fallows if you can keep your land clean; but when you fallow, do it effectually, and improve the soil at the same time by chalk, lime, or marl, according to circumstances. Do not spare either ploughs or harrows in dry weather. If you dare not trust to the drainage which the land has received, then lay the stitches high and dry before winter, and deepen the water furrows well with the spade. By following these rules the stiffest land may be brought into a good state of cultivation; and the farmer will not find, by the growth of weeds, docks, and thistles, that his labour and manure are thrown away, as is too often the case. Experience has fully proved that the air and the dews impart fertility to the soil, and that land which has been well fallowed and stirred requires less manure than it would otherwise do. Fallowing alone will not make up for want of manure, nor will manuring be sufficient without ploughing and cleaning the land properly, and exposing it to the influence of the atmosphere, especially in autumn and in spring; but a great saving of the one and the other may be effected, by judiciously varying the crops so as to admit of ploughing the land at different seasons of the year.

It is asserted by some old fashioned farmers that the plough alone is sufficient for all the purposes of fallowing. This is a great error, which leads to useless and unnecessary labour. We would almost say that ploughing the fallows is never necessary, except to enable the drags and harrows to stir the land. The first ploughing of the stubble cannot be too shallow, and the harrows should be set to work before the wet weather sets in. When the surface is become mellow and clean, the land may be ploughed deep, and the soil below should be brought up and exposed to the air and frost all the winter. In spring the drag should begin the work again before the soil is hard. It may then be ploughed in narrow ridges right across the old stitches, or obliquely, and left for the influence of summer. The drags will level all these ridges when the manure is to be put on; and this being ploughed, the land is fit to receive the seed, if wheat is the crop intended. If it is left for barley, it must have another ploughing in spring, and be well harrowed before the seed is sown, especially if this is done by the drilling-machine. The clover or grass-seeds may be sown immediately after, and the land lightly rolled. There is no danger of making it too fine in spring. Without a fine tilth no good barley can be expected.

No account of fallow operations would be complete without a reference to the Lois-Weedon system of cultivation, in which the Rev. S. Smith, incumbent of that parish, has improved upon the system of Jethro Tull, and been enabled to grow excellent successive crops of wheat in the same field for more than a dozen years. It is by far the most notable illustration of the fertilising influence of mere fallow operations which this country exhibits, and it is a remarkable thing that a practice of such proved profitableness does not more rapidly extend. The following remarks descriptive of it are taken from the 'Agricultural Gazette.'

"The Rev. Samuel Smith has now had thirteen successive crops of wheat off the same field; the last was 38 bushels, the previous one was 40, the one before was 36, the one before that was 37, 'and of prior years, beginning with 1847, the average yield may be safely given at 34.' It is not that the land is particularly fertile; it 'is really nothing but the ordinary heavy wheat land of the oolitic formation. Thousands and ten thousands of acres of the same quality extend across the country from the coast of Dorset to the Humber; and the rent of such land is under 30*s.*, being lower by 20*s.* at least than the red land of the county.' These results have not been kept a secret: they have been published far and wide—first, when agriculture was in difficulties, as 'A Word in Season,'* for such it surely was when we were all desponding over the gloomy prospect of wheat at less than 10*l.* a load; and it told us how 34 bushels of wheat could be grown perpetually on every acre of wheat land for less than 7*l.*, 2*l.* of which were rent. And these results have been published and republished, now a sixteenth time, still as a 'Word in Season,' for such it will continue to be, not only when farm profits are difficult, but so long as they are desirable. Lois-Weedon practice and experience are very generally known. Is the account of them incredible? Those who only know of them by hearsay or mere rumour may perhaps plead unbelief. Hardly any one, however, who has read the tract describing them can do so—a simpler, clearer, more straightforward statement never yet was written in the English language; and no one who knows either the locality or the author can doubt it for a moment. It is perfectly true that for the last eleven years nearly 35 bushels per acre have been annually grown upon the same land without manure, at an average annual cost, including rent and taxes (2*l.* 4*s.* 3*d.*), of 7*l.* 3*s.* 9*d.* The Lois-Weedon mode of growing wheat consists essentially in the deep cultivation (during the growth of the crop) of wide fallowed intervals between adjacent triplet rows—which intervals are the seed-bed of next year's produce. As you walk *across* the field you traverse alternate strips of plant and fallow—three rows a foot apart and then a yard-wide blank. These blanks being deeply and diligently cultivated during the autumn, winter, spring, and even summer, while the plant is sprouting, growing, and even maturing, are at once the feeding ground of the growing crop, and the store-house of food for the triplet rows of plants which next year they are to bear. These triplet rows thus yield a good average crop per acre annually and perpetually on what is really the moiety of the acre where they grow. That is the fact. Why is it not more generally acted on? It is not incredible. These fallow intervals, though unmanured directly by the hand of man, are indirectly abundantly supplied with the food the wheat-plant needs. Both ammoniacal manures and mineral manures are added in abundance. That the fertility of the soil is unimpaired is proved by the increasing crops it yields. The deep and frequent tillage brings the matter of the subsoil and the soil more thoroughly under the action of the rain water and the air, and the silicates, and phosphates, and alkalies, of which the store is practically inexhaustible, are made ready in abundance for the use of the growing plant. The porous and friable condition of the land, too, under this treatment is just such as enables the absorption and retention of the largest quantity of the ammonia of the air, and this accordingly is also furnished in abundance to the growing plant, as well as stored up for the next year's crop. There is thus nothing in the experience, when considered along with the practice, rendering it inherently improbable; or requiring us to look with more than ordinary care for the mistake which has been made. We cannot but believe that an experience at once so consistent and so remarkable will ultimately be more generally copied."

FALSE IMPRISONMENT is an unlawful arresting or imprisoning, either without just cause, or without proper legal process. In whatever manner the unlawful detention arises, it is false imprisonment, for which an action for damages lies.

When erroneous process issues out of a court having jurisdiction in the matter, a bailiff or officer who arrests a party in execution of it may excuse himself in an action for false imprisonment by showing that the court had jurisdiction; but if the court out of which the process issues has no proper cognisance of the cause, then, as the whole proceedings are *coram non judice*, the officer will be liable.

If an arrest be made by one who is not a legal officer, or who has not at the time a warrant, or is not named in it, it is a false imprisonment, for which an action lies. If a sheriff or his bailiff arrest a man out of his county, or upon a warrant of a justice whose commission has expired, or arrests the wrong party, he is liable.

Mere irregularities in lawful process may constitute false imprisonment; but in such cases the judges will discharge the party upon condition of his waiving his right of action.

All persons concerned in a wrongful imprisonment are liable in an action of false imprisonment, and the party aggrieved may sue any one of them. Thus, if the plaintiff in a suit brings an unlawful warrant to the sheriff, or if he bring a good warrant but direct the sheriff to the wrong man, the action will lie against both.

Sheriffs and their officers, high bailiffs of the county courts, constables, and other peace officers, are however protected from the consequences of a mistake by a great variety of statutes.

FALSE POSITION, a rule of arithmetic, which, though originally applied to such questions as are soluble by equations of the first degree, has been in modern writings, and upon principles explained in APPROXIMATION and INTERPOLATION applied to equations of all degrees. It is however of very little use, though of some notoriety, and a general explanation will be sufficient.

Let there be a function of x, ϕx, which it is desired to make equal to a, and firstly, let this function be such that successive *equal* increments added to the value of x produce successive *equal* increments (or decrements) in the value of ϕx (which is, in fact, supposing that ϕx is of the form $mx + n$): assume two values for x, say p and q, and let the corresponding values of ϕx be P and Q. If then (to use the easiest form of speech) a uniform increase of x is accompanied by a uniform increase of ϕx, and if x represent the value which makes ϕx equal to a, it follows that the interval between P and Q bears to that between p and q the same proportion as the interval between P and a bears to that between p and x. Or x can be obtained from the proportion

$$P - Q : p - q :: P - a : p - x.$$

If the preceding be not easily understood, the same proportion may be immediately deduced from

$$mp + n = P,\ mq + n = Q,\ mx + n = a$$

which follow from the several hypotheses made.

When ϕx and x do not increase uniformly together, it is nevertheless true that they do so *nearly* when the successive increments added to x are very small. If then p and q can be found so that P and Q are near to a, the use of the preceding proportion will produce a value of x which is nearer the truth than either p or q, and may be substituted for either in a repetition of the process, which will then produce a still nearer value.

The rule of False Position, as thus extended, is simply Brigge's and Newton's well-known method of approximating to the roots of equations, with this difference, that instead of the differential coefficient of ϕx, the approximation $(P - Q) \div (p - q)$ is used. The equation of the first degree is one in which either method will bring an accurate result in one process; but the notoriety of the rule of False Position arose out of its appearing that a couple of errors, or wrong solutions, were made infallibly to give the right result; and thus it is that Recorde says he can solve mathematical questions by taking the answers of any children or idiots who may be in the room. To persons ignorant of algebra there seems to be a mystery in the being able to make any two guesses, however remote, to discover the truth. Thus, what is that number whose half, third, and fourth, together with 10, make 62? Make any guess, say 12: the half, third, and fourth of 12, together with 10, make 23, which is wrong. Make another guess, say 60, which produces 75, also wrong. The difference of the wrong results, 75 − 23 or 52, bears to the difference of the wrong assumptions, 60 − 12, or 48, the same proportion as the excess of the result 75 over 62 (the required result) bears to the excess of 60 over the truth. But 52 : : 48 : 13 : 12, or 12 is the excess of 60 over the truth, that is, the true answer is 48, as may easily be verified.

When the equation is of the form $mx = a$, one guess only will suffice. If the assumption of p give P, or if $mp = P$, then $P : p :: a : x$.

FALSETTO, in Music, an Italian term, signifying a false or artificial voice, produced by tightening the ligaments of the glottis, and thus the vocal compass is extended about an octave higher. The Italians call the falsetto *voce di testa*, or voice from the head; the natural voice *voce di petto*, or voice from the chest.

* 'A Word in Season, or How to Grow Wheat with Profit.' By the author of 'Lois-Weedon Husbandry.' Sixteenth edition. J. Ridgway, Piccadilly.

FAN, an instrument or machine for agitating the air by the wafting or revolving motion of a broad surface, for the purpose of producing artificial currents. Large revolving fans, driven by machinery, are frequently used either to facilitate the cooling of fluids or the process of winnowing, or as blowing-machines to urge the combustion of a fire, or to assist in ventilation. Another application of such an apparatus is for the purpose of regulating or checking, by the resistance of the air to its rapid motion, the velocity of light machinery. A familiar example of such a use is afforded by the revolving fans of a musical snuff-box.

In its more ordinary acceptation the name fan is limited to the well known instrument employed by ladies for producing refreshing coolness, the use of which, under the names *flabellum* or *flabellulum* in Latin, or *ῥιπὶς* or *ῥιπιστὴρ* (diminutive, *ῥιπίδιον*) in Greek, was well known to the ancients, whose fans, however, according to the article 'Flabellum' in the 'Dictionary of Greek and Roman Antiquities,' edited by Dr. Smith, were not, like most of those now used, 'so constructed that they might be furled, unfurled, and fluttered, nor were they even carried by the ladies themselves,' so that, as the writer of that article observes, the various manœuvres so wittily described in the 102nd number of the 'Spectator' as the 'exercise of the fan' were wholly unknown to the ancients. From the numerous references given in the article above referred to, it would appear that while ancient fans were often of elegant forms, of delicate colours, and of costly and splendid materials, such as peacocks' feathers, they were stiff and of a fixed shape. Some were made of separate feathers joined at the base, and further united by a thread passing along their tips, and another tied to the middle of the shaft of each feather, and such were in use in England during the reign of Elizabeth; others appear to have been made by fastening together, back to back, the two wings of a bird, and attaching a handle at their base; while others again were formed of linen stretched upon a light frame. They were usually held by female slaves, beautiful boys, or eunuchs, whose duty it was to wave them so as to produce a cooling breeze; and the employment of such attendants was not confined to ladies, for we read in Suetonius that the Emperor Augustus had a slave to fan him while asleep. Fans of a softer kind, to which the name of *muscarium* or *μυιοσόβη* was applied, were used for driving off flies from living persons, from articles of food, and from things offered in sacrifice; and another kind of fan was employed for urging the combustion of a fire, a practice which, to conclude our quotations from the source already indicated, 'gave origin among classical writers to expressions corresponding to ours, meaning to fan the flame of hope, of love, or of sedition.'

Fans are much used in China, India, and other Eastern countries, and those of the Chinese are made to fold up in the same way as those commonly used by European ladies. Among this people fans are used by both sexes, a fan enclosed in a worked silk sheath being one of their frequent accoutrements. These are of either paper or silk, but with the Chinese, as well as the Europeans, fans are sometimes made of elegantly carved or perforated slips of ivory. Whatever be the materials employed, much skill is often displayed in the decoration of fans, and in some cases artistic talent of a high order has been applied in painting them. The mode in which they are constructed to open or fold together at pleasure is too well known to need description.

FAN MANUFACTURE. The manufacture of ladies' fans is a larger department of industry than would be generally supposed. After a considerable interval, during which fans were little used, they came again into favour a few years ago; and the manufacture is conducted in France on a large scale. The firm of M. Duvelleroy at Paris, manufactures fans for the courts not only of European countries, but for those even of Africa and Asia, amounting in some instances to the value of 1000*l.* each.

M. Duvelleroy employs many hundred persons. He has made it a point to grasp the two extremes of the scale in costliness as well as all intermediate degrees; for he makes fans from one halfpenny each to one thousand guineas. Every halfpenny fan goes through no less than fifteen hands: a proof that the factory system must be thoroughly carried out in that establishment. Duvelleroy's fans are sent to all parts of the world, and are now competing in the East with those of China. Spain is trying to maintain a home manufacture, but all the best specimens come from Paris. America affords the best markets, for while the ladies of North America closely imitate the fashions of Paris, those of South and tropical America are passionately fond of gorgeous fans, on which exciting scenes are painted in dazzling colours. Duvelleroy has a large corps of artists, who study the peculiar tastes of every nation in their pictures and colours.

In the manufacture of fans, the chief parts are called the *handle*, the *brins*, the *panaches*, the *end*, and the *leaf*. The *handle* is the part at which all the rest of the fan is hinged together, and which is made of ivory, wood, or any hard material. The *brins*, or radiants, from twelve to twenty-four in number, radiate from the handle; they are about four inches long. The *ends* are elastic pieces which connect the brins with the handle, and which form with them the skeleton of the fan; they are made of mother-o'-pearl, tortoise-shell, ivory, horn, ebony, bone, citron-wood, sandal-wood, or plain wood, and are rivetted with diamonds, gold, pearls, or more cheap material, according to the price. The *panaches* are the two outermost brins, made wider and stronger than the rest for security. The *leaf* is the surface of the fan, cut into the form of the segment of a circle. It is made of paper, of cabretille (very delicate kid-skin), vellum, parchment, satin, tulle, gauze, or crêpe, according to circumstances. There are as many folds or plaits given to this leaf as there are brins; and the brins govern the opening and closing of the leaf.

It is in the painting and decorating of the leaf that the costliness of the best fans chiefly consists. Duvelleroy has a number of highly paid and accomplished artists engaged in this department. The fans sent by that firm to the Great Exhibitions in London in 1851, and Paris in 1855, excited great attention.

FANARIOTES, a name formerly applied to the inhabitants of the Fanar or Greek quarter of Constantinople. After the capture of Constantinople by the Turks, the Greeks of the Fanar, taking advantage of the ignorance of the Turks, succeeded in rendering themselves necessary to the ministers of the Porte as translators, and to other Turkish grandees as secretaries, agents, and men of business in general. They were all comprised under the general denomination of Grammatikoi, clerks or scribes. At first they were not distinguished from common servants; and the office of the translator to the Sublime Porte conferred no consideration on the individual who held it. The Greek translator explained to the Turkish ministers the contents of a foreign despatch, after which he retired into the great hall of the palace, where he waited with other menials till his masters might want him.

In the year 1669 a Fanariot, named Panayotaki, was first appointed official dragoman, and subsequently all the dragomen were taken from their class. The Fanariotes being thus the only agents of communication betwixt the Porte and the European governments, necessarily acquired a great influence over the Turkish government, and they took good care to turn it to their own advantage. In the beginning of the 18th century the Fanariotes succeeded by their intrigues in prevailing on the Turkish government to choose from among them the Hospodars or princes of Moldavia and Wallachia, which dignities had been hitherto bestowed on natives of the above-mentioned provinces.

Mavrocordato was the first Greek who was nominated Hospodar of Wallachia in 1711. A crowd of Fanariotes always followed the new Hospodars, who employed them in different offices in their respective provinces, where they became notorious for their unprincipled exactions, employing every means, however odious, to acquire as much wealth as possible during their short and precarious tenure of office. The Hospodars, who partook of this ill-gotten wealth, countenanced and protected them in all their proceedings. The mode of government has been since changed in the above-mentioned provinces.

These were not the only sources of wealth to the Fanariote families: the bankers of the Fanar disposed of the greater part of the military and civil appointments in the Ottoman empire, through corrupt influences. An interesting picture of the Fanariotes is given in Mr. Hope's celebrated novel 'Anastasius; or, the Memoirs of a Greek;' as well as in the 'Essai sur les Fanariotes,' by Marco Zallony; and in Von Hammer's 'Constantinople and the Bosphorus.'

The events which have followed the last Greek revolution, and the subsequent events in the Turkish empire have almost entirely annihilated the Fanariotes as a class, though some Greek families are still distinguished by the name.

FANCY, a corruption of phantasy (*φαντασία*), which term in ancient philosophy indicated the sensuous appearance of an object, and in a general sense was used as co-extensive with conception, or the faculty by which man reproduces images of objects either absent or present, without an immediate impression on the organs of sensation. In later times its signification has been greatly narrowed, and it is now limited to a particular province of the imagination, with which, however, it is often frequently confounded in loose and inaccurate language, and to which it is employed as equivalent. Imagination differs from conception either by the greater distinctness and vividness of its images, or else by combining the manifold materials of experience into a new and true unity. In the former case it is merely reproductive; in the latter creative, and becomes fancy :—

> "Of all external things
> Which the five watchful senses represent
> She forms imaginations, aerie shapes."
> MILTON, *Par. Lost*, v.

Fancy is a higher energy of the mental activity than imagination simply, but is nevertheless dependent upon it, since it is the imagination that furnishes the materials out of which it creates its phantasies either by modifying or exaggerating them, or by forming new combinations, and by a prosopopœia investing its personification with the properties of real beings. Imagination is necessary to authors generally, but both imagination and fancy to the poet; the latter presenting him with those lofty speculations which comprise what has been termed the ideal of art, and furnishing the link for that enchainment of his ideas which, rejecting the restraint of all general laws, is wholly dependent upon the peculiarities of the poet's mental temperament.

FANDANGO, a quick dance in $\frac{3}{8}$ or $\frac{6}{8}$ time, much admired and practised in Spain, and supposed to be of Moorish origin; though Volney ascribes a far higher antiquity to it, believing it to have come originally from Carthage, and thence by way of Rome into Spain. The probability however is that it was brought into Europe by the Arabians, to whom certainly it may have been transmitted from remote ages. Like many other dances, this is performed with more or less propriety according to the degree of delicacy possessed by those who practise it.

FARM. A farm is a portion of land which is set apart for cultivation either by the proprietor or by a tenant who pays a certain stipulated rent for it. We shall consider it in this latter sense; and, without entering into the mode of cultivation, we shall notice the circumstances which determine the profit that a tenant may reasonably expect to make in return for his trouble and outlay.

The first thing to be considered in taking a farm is the capital which the tenant is possessed of, or of which he can procure the use at a reasonable rate. If a man takes a farm without the means of stocking it properly, and is restrained in his first outlay, he will never be able to cultivate it with benefit to himself or to his landlord: he will be obliged to sell his produce at a loss, to over-work his cattle, and to keep a smaller quantity of stock, and consequently make less manure than is required to keep the farm in a productive state. It is not sufficient that he has the means of stocking the farm; he must have wherewith to pay the greater part of the whole expenses and the rent for the first year. In the present state of agriculture, a man who takes a farm of 200 acres of arable land, or land partly arable and partly good pasture, will require from 1600*l*. to 2000*l*.; and it is not the interest, either of the landlord or the tenant, that he should take the farm unless he can command that sum. The amount of capital required depends to some extent on the quality of the land; very rich land may require less capital in proportion to the rent than poor land, especially if the poor land requires draining, chalking, or marling, before it will produce any tolerable crops. Nevertheless, the capital required may under certain styles of cultivation be in proportion to its fertility, for when grazing is the rule, the stock needed will be in proportion to the quantity of food to be consumed. All these circumstances must be taken into consideration before a farm is hired.

When it is ascertained what extent of farm may be safely undertaken with a given capital, the most important object to be attended to is the condition and fertility of the soil, not only with respect to the natural quality of the land, but the actual state it is left in by the preceding system of cultivation. A moderately fertile soil, in good condition, will give a greater profit for several years than a better soil which is partially exhausted and rendered foul by injudicious management and over-cropping. For this purpose it is necessary to ascertain what has been the state of the crops for several years before, how the land has been ploughed, and whether the crops have been heavy with or without manure. There is no method yet found out of fully ascertaining the comparative value of land which has been exhausted. It would be a question well worth the investigation of modern chemists, who have made such progress lately in the analysis of vegetable substances, and would be invaluable to farmers and proprietors of land. In the mean time the nature of the weeds which abound on the land will give some clue to its state; and an experienced person will collect from various minute appearances in the soil whether it has been fairly managed or exhausted. It is in general more advantageous to take a farm in a district with which you are well acquainted. It will be a great advantage if you have had an opportunity of seeing the land at all times, observing it in different seasons and states of the weather, and especially of seeing the crops threshed out, and ascertaining the quantity of corn which is usually yielded from a certain quantity of straw, for lands very similar in outward appearance will produce a very different return when the crops are threshed out. A want of attention to these circumstances is the cause that a man who comes from a distant part of the country and hires a farm on his own judgment seldom succeeds so well as might be expected, even with a superior knowledge of agriculture. He naturally compares the soil with some similar soil which he has been acquainted with. If he comes from a district where the soil is sandy, and where clay is in request, he will give the preference to very stiff loams; if he comes from a cold wet clay, he will prefer the sands; and the chances are, that he is mistaken in his judgment, and finds it out when he has already embarked his capital in a losing concern.

Next to the nature of the soil is to be considered the convenient situation of the farm, the disposition of the fields, and the adaptation of the farm buildings to the most profitable occupation of the land. The roads, especially those which lead to neighbouring towns, whence manure may be obtained, are a most important object; and if there is water-carriage, it greatly enhances the value of the farm. The roads to the fields, and the distance of these from the farm yard; the convenience of having good pasture, or land easily laid down to grass, near the homestead, and especially the situation of the farm-buildings with respect to the land, and the abundance of good water, are all circumstances which must be well considered, and which will greatly influence the probable profits, and consequently the rent which may be fairly offered. A central situation is no doubt the most advantageous for the farm-buildings, as greatly diminishing the labour in harvest and in carrying out manure. But there may be circumstances which render some spot nearer the extremity of the land more eligible, and it is only when entirely new buildings are to be erected that there is a choice. The old farm-buildings are generally in low and sheltered situations, but it is a great inconvenience to have to carry the manure, which is the heaviest thing carted on a farm, up a steep hill. The best situation is on a moderate slope, neither in the lowest nor highest ground.

The disposition of the buildings is of great importance both to the landlord and tenant. Large straggling buildings are inconvenient, and cost much in repairs. The house should be neat and comfortable, fit for the residence of a farmer who has a capital such as the farm requires. The rooms should be airy and healthy, facing the south, with a neat garden in front of the house. When the farmery is connected with the farm-house, there should be near the latter and the farm-yard a small paved court separated from the yard by a low wall. In this court, which should communicate with the dairy, the utensils may be placed on proper benches to air and dry in the sun. The architecture of the buildings may be left to the taste of the proprietor or his architect. The simpler it is, the more appropriate. The plan of having large yards as the main feature of the arrangement—these yards to be surrounded by the necessary buildings—is a bad one, but where it prevails they should be sheltered on the north side by the barns, which need not be so extensive as used formerly to be thought necessary. There must be a threshing machine; and a single floor to thresh the seeds upon, and to employ the men occasionally in winter, is quite sufficient. Every farm which is so extensive as to require more than one floor to thresh the corn on ought always to have a threshing-mill attached to it. [HOMESTEAD.]

Yards with sheds for the cattle to shelter themselves under in wet and stormy weather, are a great advantage, and may be added at a trifling expense to any set of farm-buildings.

For a small occupation, where the tenant is but a little above the rank of a day labourer, a set of buildings all under one roof, and forming the longer side of a yard, which may have open sheds round it, is at once convenient and economical. If this building is thought too long, it can very easily be divided into two, which may be placed at right angles to each other and form two sides (N. and E.) of a square. The farm-house and cow-house might form one side, and the stables and barns the other. This is the more common distribution in Flanders.

For a fuller reference to the subject of farm-buildings, we must refer the reader to the article HOMESTEAD. A principal thing to be attended to is to have plenty of room for cattle; and where old barns remain much larger than is required according to the present mode of stacking corn in the yard, they can be very advantageously converted into cow-stalls or ox-stables. Where many sheep are kept, it is of great advantage to have a sheep-yard, with low sheds all round, at the time when the ewes lamb, especially when the season is wet and chilly, which hurts them more than a dry frost.

In valuing the rent of a farm the habitation of the farmer is seldom taken into account, and it ought not to be above the station of the tenant; but the buildings immediately connected with the cultivation necessarily add to the rent or diminish it, as they add to or diminish the profit.

The next important question is what may be a fair rent both to the landlord and the tenant. This depends as much on the mode of cultivation adopted as on the fertility of the soil. The tenant must have a fair interest for his capital, and a fair remuneration for his trouble. In the old system a third of the gross average produce was considered as a fair rent, including all the direct payments for the occupation of the land, such as tithes, rates, and taxes; another third was supposed to cover the labour and expenses of the farm and interest of capital; and the remaining third was appropriated to the maintenance of the farmer and his family, out of which he had to save whatever he laid by as a clear profit. But this calculation is no longer applicable to the present state of agriculture. The expenses are greatly increased, and the produce is also greater. It requires a greater capital, and more skill to manage a large farm. The tenant is a man of more liberal education, and his habits are more expensive. The occupier of 500 acres of land in England expects to live as well as a land-owner of 500*l.* a year income. He cultivates better by applying more labour, and much of the produce is owing to his skill and his capital. He therefore expects a greater share of the produce than the landlord, not only to repay his outlay, which is greater, but to live upon.

In Scotland, it is notorious that rents are much higher than in England, not only for small occupations, but for extensive farms; and that the tenants have complained less of the times than their neighbours in the south. It may be worth while to inquire into the cause of this, for the low price of corn must affect the Scotch farmer equally with the English. One great difference between the Scotch and the English farmer is, that the former gets work done at a cheaper rate than the latter. The Scotch labourer is fully as well fed, and clothed, and lodged, as the English; but he has less money to spend at the alehouse. He is paid, not in a certain sum every Saturday, but in comforts, in the keep of a cow, in a certain number of rows of potatoes, a certain quantity of grain, a cottage to live in, and oatmeal to feed his family; and above all, as a general rule it must be admitted that he is a man of greater intelligence. The horses of a Scotch farmer are well fed; they are always in good condition. They work ten hours in a day at two yokings. All this is worth 25 per cent. on the whole labour of the farm, as Arthur Young has very judiciously calculated, when he gives the expense of labour on the farm of a gentleman, compared with that on the land of a farmer who works with his men. (See 'Farmer's Guide.') The moral effect of an interest in the work to be done, when opposed to that of a perfectly distinct and often hostile interest, will readily account for so great a difference

But besides this the Scotch farmer has perhaps more commonly than the English man the advantage of a scientific education, and of a knowledge of the principles of his profession; and with the shrewdness peculiar to his country, he knows how to take advantage of every favourable circumstance. He has also been taught to calculate, and will soon discover where there is a profit or a loss. All this has kept up rents to a much higher level than in England.

The price of agricultural produce throughout Great Britain, and even Ireland, is brought very nearly to an equality, the only difference being occasioned by the means of transport. But the price of labour still varies much, and this is owing to local circumstances, which it is hoped will gradually cease.

Farm Accounts.—In proportion as the management of a farm requires more skill, and the various operations become more complicated, so the necessity of great accuracy in the accounts becomes more evident. The manner in which farm accounts should be kept deserves therefore particular attention.

Many farmers, who are not devoid of intelligence, and who are anxious to ascertain their gain or their loss in cultivating the land which they have hired, have no other means of ascertaining this than the balance of their account of receipts and expenditure. If they have separated the accounts of their private establishment from that of their farm, they think that they have done all that is required, and at the end of the year they can tell accurately how much they have gained or lost by their farm. But ask them to account for this gain or loss, and they can give no answer. If a tradesman, who has a capital in business equal to that of a farmer of a considerable number of acres, were to keep accounts in this manner, and become a bankrupt, no one would hesitate in saying that he failed because he kept no regular accounts. He had no greater stake than the farmer, and his transactions were perhaps less varied: if he kept no clerk, he should have attended better to the accounts himself. The same may be said of the farmer; and if a man who has a floating capital of 2000*l.* does not think it worth his while to keep detailed accounts, it is no great wonder if he is involved in difficulties. But it may be said that agricultural accounts are very simple, and that any one can keep them. So are merchants' accounts at first sight. Nothing is simpler than to put down what is bought and sold, what is the profit on each transaction, and the sum is the profit on the whole. But merchants know that to keep this very simple account many books, many entries, many checks, and consequently many clerks, are required. In a lesser degree this is true in a farm. It is easy to know what is bought and sold; what is expended or produced; but it requires very minute accounts to ascertain what part of the farm gives a profitable return, and what is the cause of loss. There may be a profit on the crops and a loss on the stock, or *vice versâ*. The money expended on improvements or adventitious manure may have produced an increase which is proportionate to the outlay, and which affords a good interest; but it may also be a decided loss. How is this to be ascertained, except it be by accurate accounts? The expense of keeping accounts is much overrated. A clerk who has his board and 30*l.* a year is generally a young man who has some education. He is useful in seeing that the operations ordered by the farmer are duly executed. He is a trusty overseer, and, as he has his accounts in his thoughts, he is most likely to detect the cause of any loss, from a want of attention in subordinate agents; his salary is therefore well earned, and the farmer will not think it thrown away. In whatever manner the accounts are kept, whether by the farmer himself or by a clerk, method is of great importance: and whatever may be said against it by those who do not know its value, there is no system of accounts which can be compared with the well-known method of double entry, by which every account, and indeed every entry, is effectually checked. [BOOK-KEEPING.] The principle of this method is so simple, that the slowest arithmetician cannot be confused by it, and it is so perfect that no error can escape its scrutiny. As applied to agricultural accounts, which are simple in their nature, it becomes so clear, that if once adopted it is impossible that it should ever be abandoned. The satisfaction of a perfect proof of the correctness of the accounts is so great, that no one who has ever experienced it will be satisfied with any other method.

In the accounts of a farm there are many separate items to be taken into consideration. There *may* be a separate account kept for every field. There should always be one for every crop of which the rotation consists. There is an account of the labour of men and horses; of the produce of the dairy; of the stock purchased to be fatted, or sold again in an improved state. In short the divisions of the general account may be increased without limit. The more subjects there are to furnish items for an account, the more difficult it is to strike a balance, but, with a little attention and perseverance, it may be done; and he who keeps very correct accounts will always be the first to discover any impending evil, and to take measures to provide against it.

The basis of all the accounts is a daily journal of every transaction, which must be collected from all the labourers and agents employed. M. de Dombasle, at his celebrated farm of Roville, in France, had all his principal servants and his apprentices assembled every evening after the day's work was over. Each man gave an account of the work done by him or under his superintendence, which was written down by the clerk. The orders for the next day were then given, and every one returned to his lodging or his home. In the course of the next day the clerk entered all that was in the journal into a book, where every person employed had an account; every field had one; every servant and domestic animal had one; and every item which could be separated from the rest was entered, both as adding to the account or taking from it. For example, the milk of the cow was entered daily. The quantity of butter, butter-milk, and skimmed-milk, which it produced was also entered; and these two accounts checked one another. Any error was immediately detected, and the knowledge of this prevented mistakes. An entry should be made of every particular operation in each field, that the farmer may know which is his most profitable land. The number of ploughings, the quantity of manure, the state of the weather, and all other circumstances which may influence the return should be carefully noted, in order that it may be clearly seen whether any experiment or deviation from the usual routine is advantageous or otherwise. Thus all real improvements may be encouraged, and uncertain theories detected by the result.

The most important circumstance which influences the profits of a farmer is the cost of his team and the wages of his labourers. These vary in different situations so much, that they greatly influence the rent which he can afford to give for the land. In some parts of the country the horses are so pampered that they can scarcely do a day's work as they ought. In others they are over-worked and badly fed. Either extreme must be a loss to the farmer. In the first case, the horses cannot do their work, and they consume an unnecessary quantity of provender; in the other, they are soon worn out, and the loss in horses that become useless or die is greater than the saving in their food, or the extra work done by them. A horse properly fed will work eight or ten hours every day in the week, resting only on Sundays; by a judicious division of the labour of the horses, they are never over-worked, and an average value of a day's work is easily ascertained. This, in a well-regulated farm, will be found much less than the common valuations give it. It is here that most of the errors are to be detected in the accounts of the expense of cultivation given in evidence before parliament, without any intention to deceive in those who gave the accounts. There have been printed forms invented in order to render the accounts more simple as well as more comprehensive. Forms may be of use to enter minute details, and each superintendent labourer may have a form of entry for the work which he performs or superintends; but the ledger should be kept exactly as that of a mercantile man, and be frequently balanced to ensure correctness. This is a thing which cannot be too strongly recommended to young farmers.

When a farm has been agreed for as far as rent is concerned, there are always conditions in a lease, which it is of great importance to the farmer to understand fully. It is necessary that the landlord should have some security against the wilful deterioration of his land by a dishonest tenant, but agents are too apt to cramp the tenants by prescribing the exact mode of cultivation without giving the tenant sufficient scope to try improved methods, which may ultimately be highly beneficial to all parties. If the landlord can ensure that his land is in the hands of an intelligent tenant, and a man of principle as well as skill, that will secure the application of the proper quantity of manure, and that it shall be well tilled and kept free from weeds, he need not have any other protection, unless it be for the last two or three years of the lease, when the tenant might be induced to overcrop the land, and thus exhaust it.

In entering on a farm there is often a heavy demand on the in-coming tenant for work done by the predecessor, for a supposed remainder of manure, and various other items, which are usually settled by reference to the custom of the country. Some general rule is required to regulate all these demands, which are often exorbitant, and cripple the in-coming tenant in his capital. It is just that an out-going tenant should be repaid for any permanent improvement which he has made, and of which he has not reaped the whole advantage, and that he should be encouraged to keep up the proper cultivation of the land, so that the in-coming tenant may be able to continue the regular course. But this he will not do, unless he expect to be remunerated. On the other hand, it is also just that the in-coming tenant should not pay for work slovenly done, or for supposed remnants of manure which do not exist in the land. We have known instances where the valuation of all the items to be paid for by the in-coming tenant greatly diminished his capital, and crippled his operations for several years. There should therefore be a separate stipulation on this head before a farm is finally hired. [TENANT RIGHT.]

FARMERS GENERAL, Fermiers Généraux, was the name given in France under the old monarchy to a company which farmed certain branches of the public revenue, that is to say, contracted with the government to pay into the treasury a fixed yearly sum, taking upon itself the collection of certain taxes as an equivalent. The system of farming the taxes was an old custom of the French monarchy. Under Francis I., the revenue arising from the sale of salt was farmed by private individuals in each town. This monopoly was first assumed by Philippe de Valois, in 1350. Other sources of revenue were likewise farmed by several individuals, most of whom were favourites of the court or of the minister of the day. Sully, the able minister of Henry IV., seeing the dilapidation of the public revenue occasioned by this system, opened the contracts for farming the taxes to public auction, giving them to the highest bidder, according to the ancient Roman practice. By this means he greatly increased the revenue of the state. But the practice of private contracts through favour or bribing was renewed under the following reigns; Colbert, the minister of Louis XIV., called the farmers of the revenue to a severe account, and by an act of power deprived them of their enormous gains. In 1728, under the regency, the various individual leases were united into a Ferme Générale, which was let to a company, the members of which were henceforth called Fermiers Généraux. In 1759, Silhouette, minister of Louis XV., quashed the contracts of the farmers general, and levied the taxes by his own agents. But the system of contracts revived: for the court, the ministers, and favourites, were all well disposed to them, as private bargains were made with the farmers general, by which they paid large sums as douceurs. In the time of Necker, the company consisted of 44 members, who paid a rent of 186 millions of livres, and Necker calculated their profit at about two millions yearly, no very extraordinary sum, if correct. But the revolution swept away the farmers general, and put an end to the system of farming the revenues; it equalised the duties and taxes all over France; but the monopoly of the salt and tobacco has remained, as well as the duties on provisions, cattle, and wine, brought into Paris and other large towns, and the right of searching by the octroi officers, if they think fit, all carriages and individuals entering the barriers or gates of the same.

The system of farming the taxes, although generally disapproved of, is still continued in some European states. Not many years ago the custom-house duties at Naples were farmed by private speculators.

The Roman system of levying taxes, at least after the Republic had begun to acquire territory out of Italy, was by farming them out. In the later period of the Republic, the farmers were from the body of the equestrian order. Individuals used to form companies or associations for farming the taxes of a particular district; the taxes were let by the censors for a period of five years. They were probably let to those who bid highest. These farmers were called publicani, and by the Greek writers telonæ (τελῶναι), which is rendered by publicans in the English version of the New Testament, where they are appropriately classed with sinners, for they were accused of being often guilty of great extortion. These tax-collectors in the province were, however, only the agents. The principals generally resided at Rome, where the affairs of each association (societas) were managed by a director called a magister. The individual members held shares (partes) in the undertaking. There was also a chief manager in the province or district of which the company farmed the tax, who was called pro-magister.

There are no means of knowing what proportions of the taxes collected reached the Roman treasury (ærarium). Numerous complaints of the rapacity of the publicani or their agents occur in the classical writers. These publicani were the monied men of the late Republic and the early empire, and their aid was often required by the state for advances of money when the treasury was empty. Part of the maladministration probably came from the publicani sub-letting the taxes, which seems to have been done, sometimes at least.

FARTHING. [MONEY.]

FARTHINGALE, or VARDINGALE, a hoop, a circle of whalebone formerly worn by ladies to spread the petticoat to a wide circumference. Strutt, in his 'Manners and Customs,' vol. iii. pp. 84, 86, tells us that among the men, early in the reign of Queen Elizabeth, the wearing of great breeches was carried to very absurd and ridiculous lengths; and the ladies, that they might not be behind-hand with the gentlemen in fantastical taste, invented the large hoop farthingales as a companion to the trunk hose or breeches. The farthingale afforded the ladies a great opportunity of displaying their jewels, and the other ornamental parts of their dress, to the utmost advantage, and for that reason obtained the superiority over the closer habits and the more simple imitations of nature.

Bulwer, in his 'Artificial Changeling,' says, when Sir Peter Wych was ambassador to the Grand Signior from King James I., his lady was with him at Constantinople: and the sultaness, having heard much of her, desired to see her; whereupon Lady Wych, accompanied with her waiting women, all of them dressed in their great farthingales, which was the court-dress of the English ladies of that time, waited upon her highness. The sultaness received her with great respect: but wondering much at the extension of her hips, inquired if that shape was peculiar to the women of England; to which the lady replied, that the English women did not differ in shape from those of other countries: and, by explaining to her the nature of the dress, convinced the sultaness that she and her companions really were not so deformed as they appeared to be. (Strutt's 'Habits of the People of England,' vol. ii.)

The farthingale, however, if not then, was at least subsequently worn through Europe. The French farthingale had the name of *Hausse-cul*; see Cotgrave. Lascells, in his 'Voyage of Italy,' 12mo., 1655, p. 96, says, "I found all the great ladies here to go like the donnas of Spain in guardinfantas, that is, in horrible overgrown vertigals of whalebone;" and Pepys, in his 'Diary,' notices the strangeness of those worn by the ladies who came over from Portugal with Charles the Second's queen. The hoop, the successor of the farthingale in England, went out at the beginning of the reign of George IV., who forbade its being worn at court. In 1858 and 1859 a modified revival took place. The hoop was no longer worn of the same size from the hips, but, under the name of crinoline, began a little larger than the body and swelled to an enormous size near the feet.

FASCES. [CONSUL; DICTATOR.]

FASCINES (*Military*) are bundles of strong brush-wood, employed chiefly for the purposes of reveting the epaulements of batteries and covering the roofs of field-magazines and blindages; and also with gabions to increase the heights of trench parapets, and to make temporary roads over marshy ground.

They are formed by placing the rods side by side in a cradle made of trestles placed about 4 feet apart, and compressing them by means of two levers connected by a chain, which is passed round the bundle: the whole is secured by withs or binders of spun yarn, which are placed 18 inches asunder. Fascines are commonly about 8 or 9 inches in diameter, and, when made, are 18 feet long; but they are then, if necessary, cut by the saw into parts of any required lengths, which are generally 6 feet or 12 feet. A fascine of the longest kind is sometimes called a saucisson.

When fascines serve for the revetment of a battery, they are usually laid horizontally, one line above another, against the interior slope of the epaulement, to which they are attached by pickets driven through them into the earth.

FASCINES, in *Civil Engineering*. A species of light defence (applied to the earthworks thrown up for the purposes of closing small branches of rivers, or of regulating the flow of the water), composed of small twigs bound together in bundles, and fastened to the ground by means of stakes and withes, is known among civil engineers by the name of *fascine work*. The bundles of twigs are made from the clearings of underwood and of dwarf trees, such as the ash, oak, hazel, alder, willow, thorn, bramble, &c., of about six or eight years old, the butt ends of which are all placed at one end, and in no case should the branches exceed 4 or 5 inches in diameter. The diameter of the bundles may vary between 1 foot 6 inches to 4 feet 6 inches at the larger end, and their length would, under these circumstances, range between 5 and 10 feet; the twigs being retained in their position by means of withes (or twisted twigs which tie the bundles together), placed at intervals of from 1 foot 4 inches to 1 foot 8 inches from one another. These bundles, or fascines, are either placed by hand upon the surface to be protected, or they are formed into species of rafts which are floated over the position they are intended ultimately to occupy, and are then sunk upon it, by being loaded with stones or gravel. The stakes or pickets are then driven through the bed of fascines into the bank, and they are connected together by stouter withes, which pass alternately round the heads of the stakes, in such a manner as to form square cases, to be subsequently filled in with rubble. It is supposed that the species of matting thus formed adapts itself with ease to the irregularities of the surface of the earthworks; but its principal advantage seems to consist in the fact, that it distributes the weight of the pitching course over the whole area, and thus prevents it from sinking into the body of the earth.

Fascines are much used by the Dutch, German, and French engineers; especially in the works executed for the protection of the banks of the Rhine. A description of the various systems adopted in the hydraulic works of that river will be found in 'Les Annales des

Ponts et Chaussées,' for 1833; or the reader may refer to Belidor's 'Architecture Hydraulique,' or to Sganzin's 'Cours de Construction, edité par Reibell.' Sometimes civil engineers of the Continent employ large fascines, which form, in fact, baskets filled with gravel, and are known by the local name of *saucissons;* or they use large square or triangular prisms to form the hearting of their banks. It is on the shores of the Lower Rhine especially that the fascines are formed into gigantic rafts, as above mentioned, of from 3000 to 4000 yards superficial, which are subsequently floated over their intended position, and sunk by the addition of gravel, or stone pitching. The Dutch engineers frequently use bundles of reeds for the same purposes as the fascines, at least in the protection of exposed surfaces of their dykes; whilst they also occasionally line the surface of a slope, intended subsequently to be pitched, with bundles of straw, when the price of fascines is so great as to render their use impracticable.

FAST, abstinence from food, more particularly used for such abstinence as a religious observance; from the Anglo-Saxon *fæstan.*

Religious fasting has been practised in almost all ages and all countries. Moses appointed that of the Day of Expiation for the Israelites. Herodotus (ii. 40) and Porphyry, give us details of the Egyptian fasts. Among the fasts of the primitive Christians, the greatest was that of Quadragesima, or Lent: but they likewise observed the *Jejunia quatuor temporum*, or fasts of the four seasons.

The fixed days appointed by the church of England for fasting are, first, the Forty days in Lent: second, the Ember days at the four seasons, being the Wednesday, Friday, and Saturday, after the first Sunday in Lent, the Feast of Pentecost, September 14th, and December 13th; third, the three Rogation days, being the Monday, Tuesday, and Wednesday before Holy Thursday; fourth, all the Fridays in the year except Christmas-day. Other days of fasting are occasionally appointed by royal proclamation. The Long Parliament appointed a fast on the last Wednesday of every month.

The Roman Catholics, the Greek Church, the Jews, the Mohammedans, the Buddhists, all keep certain fasts, as a religious observance; that of the Mohammedans being very severe.

FASTI were marble tables at Rome, on which were inscribed the names of the consuls, dictators, censors, and other principal magistrates of the republic. Fragments of these tables have been collected, and are ranged along the walls of one of the halls in the palace of the Conservatori on the Capitol. The deficiencies in the series of the consuls have been supplied by means of the historians, and by consulting monumental inscriptions. Several learned men in modern times have compiled fasti, or chronological tables of the Roman consuls. Among the most learned and accurate of these compilers is Sigonio of Modena, who published his 'Fasti Consulares ac triumphi acti a Romulo rege ad Titum Cæsarem,' fol., 1559; with a dissertation 'de nominibus Romanorum,' a work of great erudition and exact criticism. Pighius published 'Annales Magistratuum et Provinciarum S. P. Q. R. ab Urbe condita,' fol., 1599. Labbe, in his 'Bibliotheca Nova,' published 'Fasti Consulares' out of a MS. of the college of Clermont. Other editions of the Fasti have been made from various sources. Between these lists occasional discrepancies occur as to the names of some of the consuls, and the particular years of their consulships; for, notwithstanding the labours of critics and antiquaries, there is still some uncertainty about Roman chronology. The word Fasti is often used as synonymous with the annals, or chronicles of a nation. The 'Fasti Hellenici,' and 'Fasti Romani,' by H. F. Clinton, are valuable works of this description. [Clinton, H. F., in Biog. Div.]

The Romans had another kind of fasti, which they called 'Fasti minores,' a kind of almanacs, in which were registered the periodical festivals, games, official days for business, &c. Ovid wrote a poem explanatory of these fasti, which he dedicated to Germanicus, and in which he described the origin of the festivals, and the recollections, either happy or calamitous, connected with the various days of each month. The poem, as we have it, is in six books, one for each of the first six months in the year; the rest is unfortunately lost.

FASTING. [Abstinence.]

FATA MORGANA. [Reflexion and Refraction, Extraordinary Atmospheric.]

FATALISM. This term is used to express an article of philosophical religion, and usually signifies that the successive actions of mankind, and even the successive operations of the powers of nature, are under the guidance of some superior almighty power, so that these *successions* and the actions themselves are entirely independent of each other. This doctrine has been embodied in all religious systems, though very different names have been given to the governing power. The Greeks called it *moira* or *ananke*, and the Romans called it *fate;* their mythology also mentions a Demiurgus, who had formed the gods. All the ancient religions of Asia recognise a similar fate, something mightier than the gods, to whom it dictates laws; such, for example, as the alternating governments of Ormuzd and Ahrimanes in the Persian mythology, &c. Among the Hebrews the Pharisees were fatalists, the Sadducees materialists, and the Essenes deists. The old Germanic religion of Odin modified this fate, and brought it nearer to the idea of the government of the world by a deity, identifying it with their highest god, whose name was not to be pronounced. From this point fate changes to what is called predestination (in opposition to chance), which idea is only a mitigated fate, distinguished, however, from genuine fatalism in proceeding directly from God, and not from fate. This belief in predestination was taught by Mohammed, and his followers have retained it. Roman Catholicism has no trace of this doctrine, but it is held by the Calvinists, and to a certain extent at least by the church of England.

The doctrine of fatalism, as is well known, has been frequently and effectively used both by ancient and modern poets.

Intimately related to fatalism is the doctrine of the immediate and direct intervention of Providence in the government of the world. According to this doctrine the *consequences* of the actions of mankind depend wholly upon the actions themselves; God, however, is able so to conduct these consequences, that collectively they shall result in good, and conformably to his purpose. To comprehend this working precisely is impossible for man, since his mental powers are not sufficiently extensive, and this dogma must therefore be a matter of faith. This doctrine is held by many Christian sects, and in the Bible there are passages strongly in favour of such special intervention; for example, Matthew x. 29, "Are not two sparrows sold for a farthing? and one of them shall not fall on the ground without your Father."

The third or deistical interpretation of this doctrine teaches the complete non-intervention of the Deity in the affairs of the world or of mankind: we may also call this doctrine the doctrine of theological chance, which may still be consistent with that of physical necessity, according to Kant. The doctrine of physical necessity was advocated by Hobbes, and served for the foundation of the charges against him of deism and atheism.

If we consider these doctrines in a philosophical point of view we may come to the following results:—The theological theories of fatalism, predestination, the immediate government of God, and his non-intervention, evidently bear an analogical relation to the political systems of despotism, constitutional monarchy, and republicanism. Accordingly as every one may have grounds for being an adherent of one of these political systems, so may he also have grounds for being a follower of one of these theological views. According to the ideas and investigations of the author of this article, God may have positively fixed, before any creation of the world, the eternal ideas, or the relations of things to each other within the circle of which nature and human intelligence have to move. These ideas are (1) for nature, self-preservation, or continuance, of which the product is attraction, &c.; regularity, producing crystallisation, &c; and adaptation to purposes, producing organisation, &c.; (2) for human intelligence, self-love, beauty, and virtue. In so far as nature and humanity with all their efforts cannot move out of this sphere of ideas, so far fatalism and predestination exist. The efforts of nature to adapt means to ends, and the endeavours of the wise after virtue (or human happiness) appear to produce an ever-increasing progression, and in this sense they constitute an intervention of Providence—since nature being wholly bound, and God absolutely uncontrolled, man stands between both; so that though he is not absolutely free, yet he is free to work his ultimate ends out of himself; he is free whenever he acts morally, and he is not free whenever he acts immorally (or rather physically), and he may thus arrive at the consciousness that his state in another world entirely depends on himself. With this conviction every species of intervention would appear less harsh towards him, and without these grounds he may be doubtful whether any direct intervention exists with respect to worldly affairs.

An intervention of any other kind than that of God would lead to the doctrine of demons and spirits.

FATHER. [Parent and Child.]

FATHERS OF THE CHURCH is the name given to the early teachers and expounders of Christianity, who lived between the second and the sixth centuries of our æra, and whose writings are looked upon as possessing considerable authority in matters of faith. The earlier, or "primitive fathers," as they are sometimes styled, to distinguish them from the fathers of the fourth and fifth centuries, and who followed close upon the apostolical age, or the age in which the Apostles lived and died, are generally reckoned as follows. 1st, Clemens Romanus, or Clement I., bishop of Rome, who died about A.D. 100. 2nd, Ignatius, bishop of Antioch. 3rd, Polycarpus, bishop of Smyrna. 4th, Justinus, or Justin Martyr. 5th, Theophilus, made bishop of Antioch about 169, died about the beginning of the reign of Commodus: there is extant by him a work in three books, addressed to Autolycus, a heathen friend of Theophilus, whom he endeavoured to convert to the Christian faith. 6th, Irenæus, bishop of Lyon. 7th, Clemens, Titus Flavius Alexandrinus. 8th, Cyprian, bishop of Carthage. 9th, Origen of Alexandria. 10th, Gregorius, called Thaumaturgus. 11th, Dionysius, bishop of Alexandria, also a disciple of Origen: was banished under Valerian to the deserts of Libya, but was restored to his see under Gallienus, was engaged in controversy with Sabellius, Nepos, and Paul of Samosata, and died A.D. 265: of his numerous writings only fragments remain. 12th, Tertullianus of Carthage.

We now come to those Fathers of the Church who flourished in the fourth century, after Christianity had become the religion of the Empire, an age which may be styled the Augustan age of ecclesiastical literature, for the number and the merits of the writers whom it produced. The fathers of this period are generally ranged in two classes—Fathers of the Greek or Eastern Church, and Fathers of the

Latin Church. The former are: 1st, EUSEBIUS of Cæsarea. 2nd, ATHANASIUS, bishop of Alexandria. 3rd, BASILIUS, bishop of Cæsarea. 4th, GREGORIUS of Nazianzus. 5th, GREGORIUS, bishop of Nyssa. 6th, CYRIL, bishop of Jerusalem. 7th, CHRYSOSTOM, ST. JOHN, patriarch of Constantinople. 8th, EPHIPHANIUS, bishop of Salamis. 9th, CYRIL, bishop of Alexandria. To the above must be added Ephraim the Syrian, deacon of Edessa, who died about 378, and whose works have been published in the original text by Assemani.

The Fathers of the Latin Church are: 1st, LACTANTIUS. 2nd, HILARIUS, bishop of Poitiers. 3rd, AMBROSE, archbishop of Milan. 4th, JEROME, the translator of the Bible. 5th, AUGUSTINE, bishop of Hippo. With Augustine the list of the great Fathers of the Church is generally considered as terminating, although this title has been also bestowed on some subsequent prelates and theologians; but these, such as Bernard, Thomas Aquinas, &c., are more properly distinguished by the name of Doctors of the Church.

Of all the fathers whose names in the foregoing lists are printed in small capitals there will be found notices in the BIOGRAPHICAL DIVISION.

The study of the Fathers is interesting and important not only to theologians, but to those who would examine carefully the philosophy and the state of society in their time.

FATHOM. [WEIGHTS AND MEASURES.]

FATTY ACIDS. Fats and fixed oils consist for the most part of glycerin united with an organic acid, and when such fats and oils are boiled with basic substances, especially with the alkalies and alkaline earths they are decomposed, the acid uniting with the base, whilst the glycerin is set at liberty. This process of decomposition is commonly termed *saponification*, because it is the one essentially employed in the manufacture of soaps. The acids thus extracted from the fats and oils are frequently spoken of under the name of *fatty acids*. They belong to two distinct groups of organic acids, namely, to the series having the general formula, $CnHnO_4$ and to that having the general formula, $CnH(n-2)O_4$. By the action of oxidising agents upon some of the members of these groups, a third family of acids of the form $CnH(n-2)O_8$ is produced. The acids belonging to the latter family are bibasic. The following list gives the names and formulæ of the members of these three series of acids :—

Acids having the formula $CnHnO_4$. Monobasic.	Acids having the formula $CnH(n-2)O_4$. Monobasic.	Acids having the formula $CnH(n-2)O_8$. Bibasic.
Formic . $C_2H_2O_4$		
Acetic . . $C_4H_4O_4$	. . . . .	Oxalic . . $C_4H_2O_8$
Propionic . $C_6H_6O_4$	Acrylic . $C_6H_4O_4$	
Butyric . $C_8H_8O_4$	. . . . .	
Valerianic . $C_{10}H_{10}O_4$	. . . . .	Succinic . $C_8H_6O_8$
Caproic . $C_{12}H_{12}O_4$	Angelic . $C_{10}H_8O_4$	Adipic . $C_{12}H_{10}O_8$
Œnanthylic $C_{14}H_{14}O_4$	. . . . .	Pimelic . $C_{14}H_{12}O_8$
Caprylic . $C_{16}H_{16}O_4$	. . . . .	Suberic . $C_{16}H_{14}O_8$
Pelargonic $C_{18}H_{18}O_4$		
Rutic . . $C_{20}H_{20}O_4$	. . . . .	Sebacic . $C_{20}H_{18}O_8$
Lauric . . $C_{24}H_{24}O_4$		
Myristic . $C_{28}H_{28}O_4$		
Palmitic . $C_{32}H_{32}O_4$	Physetoleic $C_{32}H_{30}O_4$	
Stearic . . $C_{36}H_{36}O_4$	Oleic . . $C_{36}H_{34}O_4$	
Arachidic . $C_{40}H_{40}O_4$		
Cerotic . . $C_{54}H_{54}O_4$		
Melissic . $C_{60}H_{60}O_4$		

Detailed descriptions of these acids will be found under their respective names.

FAULT. [MINING.]

FAUN, FAUNUS, was the name given in the Roman mythology to the gods or genii of the woods, corresponding with the Panes of the Greek mythology. The Fauni were supposed to be the descendants of Faunus an old mythical king of Latium, who resided in the forest Albunea with his wife Fauna or Fatua, near the pond of sulphureous water which is between Rome and Tivoli; and who were both gifted with the faculty of prophesying. In subsequent ages Faunus was worshipped as the god of the fields and flocks; and a festival, called the Faunalia, held in honour of him by the country people and agriculturists on the 5th of December, was a scene of great mirth and feasting. The forest of Albunea continued to be the Delphi of Latium, and the oracles were delivered by a voice issuing from its recesses. (Virgil, 'Æneid,' vii. 82, &c.) Several statues in most European museums are believed to represent Fauni, but many usually called Fauns were more probably intended for Greek satyrs. [SATYRS.] Among the most remarkable are those in the gallery of Florence, and a very handsome one in the museum of the Capitol. The sleeping Faun of the Barberino is now in the gallery at Munich. The so-called Rondinini Faun in the British Museum is a very fine statue of its class: it is of the size of life, and in a dancing attitude, but the head and extremities are modern. This statue was formerly one of the most remarkable objects in the Rondinini palace at Rome. It was brought to England in 1826: and it would, it is said, have been brought here several years earlier, had not Canova used his influence to prevent its leaving Italy. Another very fine figure of a faun or satyr in the British Museum is that known as the 'Laughing Faun,' but the arms and both the legs below the knees are the work of a noted Italian "restorer" named Algardi, and are quite inconsistent with the original torso. A third, and equally celebrated statue in the same collection is that of a faun or satyr lying on his back, and known as the 'Drunken Faun': of this also the right arm and both feet are a restoration. There are some other statues and relievi of fauns in the British Museum which will sufficiently illustrate their general character: they are mostly collected in the Third Græco-Roman Saloon. The Fauni are almost invariably represented in playful attitudes, with a wild, mirthful, transient expression. Flaxman has in a single sentence sufficiently characterised them. "The Fauns are youthful, sprightly, tendonous; their faces round, expressive of merriment, not without an occasional mixture of mischief." ('Lectures on Sculpture,' p. 152.)

Rondinini Faun from the British Museum.

FAUSSE-BRAYE, a name given to the rampart which, constituting a second enceinte, is sometimes formed on the exterior of and parallel to that which constitutes the principal enceinte of a fortress.

In the ancient fortifications a bank of earth was frequently raised in the ditch, nearly or quite contiguous to the wall of stone or brick surrounding the place, in order to protect the latter against the battering-engines of the besiegers; and the Italian engineers of the 16th century make mention of a detached wall of masonry similarly situated, which seems to have been intended for a like purpose. This was then called a *fossa-brea*, and subsequently, by the French engineers, a *fausse braye*; the first term indicating a covering work in the ditch, and the other simply a secondary or advanced rampart.

In and immediately before the time of Vauban the fausse-braye constituted the exterior part of the general rampart of a fortress; its terreplein, or upper surface, was on, though sometimes a little above or below, the level of the country, and it carried a parapet for the protection of the defenders. The terreplein and parapet of the interior part of the rampart were several feet higher than those of the fausse-braye, and the interval between the two parapets was sometimes broad enough to allow room for artillery.

A good indication of the nature of this work may be obtained from the lower flanks of the bastions at Portsmouth, which are *double flanks*, and, in order to render the example complete, it is merely necessary to suppose these second parapets continued along the curtains and before the faces of the bastions.

The fausse-braye, thus formed, was most probably employed before the introduction of the covered way, a far more useful work: for the terrepleins and crests of parapets of the two works being in the same horizontal planes, it is evident that the fires could not be simultaneous, and consequently that neither the musketry nor artillery fire of the fausse-braye could be employed till the enemy were on the crest of the glacis. It also afforded to the enemy some facilities in escalading the rampart, by breaking the revetment into two steps, as it were; the first one, that of the fausse-braye, being about twenty-two feet, and when the enemy were on it permitting him to circulate along the rampart and rush in at more points than one at the same time. And again, the defenders of the fausse-braye would be easily enfiladed by the enemy's lodgments on the crests of the glacis three or four feet above them; and would be much injured by his shot and shell, which, striking the revetments behind them, would cause great splinters, and choke up the terreplein. On account of these defects, this kind of fausse-braye has been long since suppressed, except opposite the curtain, where it is supplied by the tenaille. [BASTION, *fig.* 1.] It should be observed, however, that Carnot and other more recent French engineers have proposed constructions which may be considered as partial revivals of the fausse-braye, but with circumstances which appear to render the work free from the defects above mentioned.

FEALTY. [FEUDAL SYSTEM.]

FEAR is the dread or apprehension of any object or event, which object or event however is sometimes purely imaginary. Absence of fear is resolution or courage. Absence of all *dread* would be a repose of the soul, for which, as it cannot exist, the language affords no term. Dread is a minor species of affright or terror, but of a more enduring nature. The highest and most excessive state of terror amounts to a total deprivation of consciousness, and produces death. If these definitions are correct, a smaller degree of terror would consist in a quickly-passing unconsciousness. Dread would consequently consist of a succession of recurring periods of unconsciousness, alternating with excessive rapidity with intervals of consciousness, of which only the total impression is perceived (as in the vibratory strokes of vibrating bodies in acoustics); this total impression constitutes dread. Fear is only distinguished from dread through the imminence of danger, and thence a fearful or a dreadful or frightful object are nearly synonymous. The longer these periods of unconsciousness endure in a state of fear or dread, the more powerful are the feelings, till at length (as in drowning persons, or in children who are much alarmed) total unconsciousness ensues, and, according to circumstances, death.

If these definitions of fear and dread are psychologically correct, they serve to explain all the consequent physiological phenomena. A violent blow upon the head deprives us of consciousness, by occasioning an interruption in the regular functions of the brain, through which recollection ceases, and unconsciousness ensues. Any horrible appearance to, or impression upon, the organs of sight may produce a similar effect; for if the nerves of vision are so powerfully affected as to re-act upon the brain, the regularity of its action is similarly destroyed and the same effects are produced as by a blow. It is the same with all the other senses; and it is worthy of remark, that these feelings (of fear or dread) evidently heighten the powers of the imagination. If therefore a powerful affection of the visual nerve will produce absolute terror, so may a smaller degree of terror produce the more lasting sensations of dread or fear, that is, interchanging pauses of consciousness and unconsciousness. With the brain and spinal marrow the nerves are connected which lead to the lungs, to the stomach, to the muscles, and other parts of the body. It is therefore not surprising that dread or fear should display itself in shortness of breath, irregularity of pulsation, an increased action of the heart, a disordered stomach, sickness, and powerlessness of the limbs.

Fear may be also produced through a disordered action occasioned by some local affection of the heart or the lungs, or through plethora or disorders of the blood, or through a general sickness, as in the cholera.

FEAST or **FESTIVAL**, an anniversary day of civil or religious joy; from the Latin *festum*.

Among the Jews, the feast of Trumpets, that of Expiation, the feast of Tabernacles, the feast of Dedication, the Passover, Pentecost, and the feast of Purification, were the principal. The modern Jews have a few more, but they are of later institution.

The Greeks, and more especially the Athenians, had an abundance of festivals. Such were the Aglauria, in honour of Aglauros, the daughter of Cecrops; the Artemisia, in honour of Artemis; the Dionysia, in honour of Dionysus; the Eleusinia, in honour of Ceres; and the Panathenæa, in honour of Athene: notices of the three last and most important of them will be found under their several headings.

The Roman festivals were of two kinds; first, those which were fixed or stated; secondly, those which were appointed annually on a certain day by the magistrates or priests. Of the former kind were the Agonalia, the Faunalia, Matronalia, Cerealia, Saturnalia, &c., through the several months; the latter were the Feriæ Latinæ or Latin holidays, the Paganalia in honour of the tutelary gods of the rustics, the Sementivæ in seed-time, and the Compitalia. Dion (ix. 17) observes that so large a portion of the year was taken up with sacrifices and holidays, to the great loss of the public, that Claudius abridged the number.

The Mohammedans, in addition to their weekly feast, or sabbath, which is observed on Friday, have two festivals of a more solemn kind; the feast of Victims, celebrated on the 10th day of the last month of their year, and the feast of Bairam.

With us, some of our festivals are immoveable, and others moveable. The immoveable festivals are Christmas Day, the Circumcision, the Epiphany, Candlemas or the Purification, the Annunciation of the Virgin Mary or Lady Day, All Saints, and All Souls. The greater part of what are called Saints' Days have long ceased to be celebrated, except in the calendar. The principal of the moveable feasts, and that by which the rest are guided, and from which they keep their proper distance, is Easter; the others are Palm Sunday, Good Friday, Ash Wednesday, Sexagesima, Ascension Day, Pentecost, and Trinity Sunday. The four feasts from which leases are usually dated, and quarterly payments made, are Lady Day, 25th March; the Nativity of St. John Baptist, June 24th; Michaelmas Day, September 29th; and Christmas Day, December 25th. In the Roman Catholic and Greek churches the festivals of the various saints are still preserved.

The reader who would know more of the English festivals at an earlier period, may consult the 'Liber Festivalis,' printed at Westminster by W. Caxton, sm. fol. 1483, which consists chiefly of a collection of sermons, preached to the common people upon them. See also 'Festa Anglo-Romana,' 12mo, London, 1678; 'Historia Sacra, or the Holy History, giving an exact and comprehensive account of all the Feasts and Fasts of the Church of England,' 2nd edit.; and Nelson's 'Fasts and Festivals.'

FEATHERS. In addition to their anatomical relation to the coverings of birds, the principal uses to which feathers are applied are for personal decoration, as plumes for ladies' head-dresses, or for the hats of military officers; as a soft and highly elastic material for filling beds, cushions, and pillows; or in the case of the larger quill-feathers, as writing-pens, or small tubes for the manufacture of hair-pencils, or similar purposes.

For the first of these purposes their elegant appearance is their great recommendation; for the second, to which only the smaller feathers are applied, their exquisite softness, and that elasticity and peculiarity of structure which renders them less liable to clot together, under the influence of pressure, than any kind of woolly or hairy substance which is applied to the same purpose, are their great recommendation; while the last-mentioned use depends on their possession of a hollow quill or barrel of a horny texture, which, though found in all feathers, is only sufficiently large and strong in those of the wings and tail to be useful for such a purpose.

Plumagery. Of the various kinds of feathers employed as plumes for head-dresses, the most important are those of the ostrich, of which there are various qualities, almost wholly procured from Africa. Those of the male bird are preferred, as being the whitest and most beautiful; those upon the back and above the wings being considered the best, those of the wings next in quality, and the tail-feathers the least valuable. The *down*, which is black in the males and gray in the females, consists of the smaller feathers from other parts of the body, which vary in length from four to fourteen inches. The finest white feathers of the female bird are somewhat gray towards the end, which lessens their value. The mode of preparing ostrich feathers for use, and of dyeing them of various colours, is briefly as follows: They are first washed or *scoured* by rubbing with the hand (being previously tied up in bundles) in a lather of white soap and water, and subsequently in clear water, as hot as the hand can bear. They are then bleached by three successive operations, the first being to immerse and agitate them well in hot water mixed with Spanish white, after which they are rinsed in three clear waters in succession; the second, which is termed *azuring*, passing them quickly through a bath of cold water containing a little indigo tied up in a fine cloth; and the third, *sulphuring*, or exposing them in a close vessel to the vapour of burning sulphur, in the same way as in the bleaching of straw hats and bonnets. The feathers are then dried by hanging upon cords, during which they are shaken from time to time to separate their fibres. To increase their pliancy the ribs are scraped with a bit of glass cut circularly; and to impart the requisite curly form to the filaments or fibres, the edge of a blunt knife is drawn over them. The dyeing is effected by various agents—logwood, copperas, and acetate of iron for black; indigo for blue; alum, Brazil wood, and cudbear for crimson; safflower and lemon-juice for pink; alum and Brazil wood for red; alum, turmeric, and weld for yellow, &c. For all colours except black, the feathers should be previously well bleached by exposure to the action of sun and dew, which is effected by cutting the end of the quill or tube to a sharp point, and sticking or planting the feathers singly in grass ground, where they are left for fifteen days.

Dr. Macgowan, United States consul at Ningpo, has recently given an interesting account of the plumagery or feather-working of the Chinese. Feathers are largely employed by that ingenious people in the decoration of metallic ornaments, chiefly for head-dresses. The lustre of the metal is softened by laying over it portions of a covering of blue feathers, representing flowers, insects, birds, and the like. The art appears to most advantage as practised by artificers whose occupation is the manufacture of garlands, chaplets, frontals, tiaras, and crowns of very thin copper, on which purple and blue feathers of gorgeous brilliancy are placed with much taste and skill. From the size of these ornaments, scope is afforded for the display of various figures. Dr. Macgowan describes in the following words the processes of this kind of feather-working :—"On the table at which the workman sits, he has a fasciculus of feathers, a small furnace with a few embers for keeping warm a cup of glue, a small cutting instrument like a screw-driver, a pencil or brush, and the articles, either silver, gilt, copper, tinsel, or pasteboard, which are to be feathered. The thumb and index finger being smeared with glue, the feathers are gently drawn between them, which stiffens the barbs, causing them to adhere firmly together; when dry, the perpendicular blade is drawn close to the shaft, dividing it from the barbed portion. Holding this cutting instrument as in writing *à la Chinoise*, the artist, by pressing on the strips of barb with the knife, cuts them into the desired size and shape, which is a work of some delicacy—the pieces being very small, in the form of petals, scales, diamonds, squares, and the like, and requiring to be of the same size as the particular spot on which they are to be laid. Besides fingering this tool in the manner described, he holds the pencil nearly as we do a pen, dips it into the glue, brushes the spot to be coated; then expertly reversing it, touches with its opposite point a morsel of feather, which is thus lifted up and laid on the part for which it was fitted. Care is requisite also in giving a proper direction to this twilled work; for such of course is the appearance presented by the barbs. The feathers most in demand for this purpose are from a beautiful species of *Alcedo*, brought from the tropical regions of Asia; they are employed for silver articles. Kingfishers of coarser plumage, and less brilliant hue, found throughout the country, are used for ornaments made of copper and pasteboard. Blue always greatly predominates over lighter or darker shades, relieved by purple, white, or yellow. . . . Sometimes two dragons extend from below the lobes of the ears, meeting above the forehead, the variegated scales of which are represented by minute portions of feathers of various hues; at others, beautiful flowers are interspersed with elegant mosaic. And then again the head attire appears animated; as with every turn of the fair one, tiny genii, birds, and insects are set in motion from springs and wires which retain them in the midst of the fairy-like garland. To increase the effect, these ornaments are studded with pearls, produced cheaply and in great abundance by artificial means in a fresh-water mussel." ('American Journal of Science and Art.')

Bed Feathers. The employment of feathers for stuffing beds was known in England at least three centuries ago. Goose feathers —which, owing to their superior elasticity, are preferred for this purpose—are considered best when plucked from the living bird; and in the districts where geese are chiefly kept, this cruel operation is repeated from three to five times in a year. While most writers condemn this practice for its apparent barbarity, and while some even assert that in cold weather many birds die in consequence of being subjected to it; others affirm, on the other hand, that the breeders, for their own profit, pluck only such feathers as are very near falling off, and the removal of which consequently gives but little pain, because as such as are firmly fixed have a little blood at the end, they are less valuable. Young birds are plucked as well as those of mature growth, early plucking being supposed to promote the rapid growth of the feathers. Goose feathers are divided into white and gray, the former being deemed the most valuable. The less valuable kind of feathers, known by the general name of *poultry feathers*, are obtained from turkeys, ducks, and fowls. Wild-duck feathers are both soft and elastic, but their value is impaired by the great difficulty of removing the disagreeable odour of the animal oil which they contain. Various methods are practised of cleansing feathers from their oil. Some manipulators use lime water; others lime in a different state. The purification of bed-feathers by the agency of steam is now much practised; in one method, which is secured by patent, and is applicable either to new feathers or to such as have become deteriorated by use, the feathers are so greatly improved in softness and elasticity that a much less quantity of them than of feathers prepared in the ordinary way suffices to make a good bed.

The softest and finest kind of feathers employed for bedding are those from the breast of the eider-duck, known in commerce as eider-down. [EIDER DOWN.] This exquisitely soft down should never be slept upon, as it thereby loses its elasticity, but should be used only as a covering. A similar substance, though in less quantity, is procured from the swan, the goose, and some other birds.

Quills for Pens. For the third of the above-mentioned uses of feathers the quills of the goose are most generally employed, though, for purposes where great size and strength are required, those of the turkey and swan are highly prized. When geese are plucked several times in a year for other feathers, the quills are only taken at the first plucking about the end of March. As taken from the bird, the horny substance of the barrel of the quill is covered, both internally and externally, with a vascular membrane, which adheres very closely to it, and the substance of the quill itself is opaque, soft, and tough. The quills must therefore be subjected to certain operations by which the membranes may be detached and dried up, and the barrel rendered transparent, hard, and somewhat brittle; previous to which they are sorted into *primes*, *seconds*, and *pinions*, the first of which consist of the largest and longest barrelled quills, and the others of such as possess these characteristics in a less degree. They are further sorted into right and left wing feathers, in order that all tied up in one bundle may have the same curvature; and before tying up for sale the *barb*, or feather proper, is usually stripped off from the inner edge of the stem, in order that they may lie compactly together. In a goose's wing only the five exterior quills are fit for making pens, and of these the first is the hardest and roundest, but the shortest, and the second and third are considered the best. Dutch quills are highly esteemed, as the Dutch were the first who hit upon the art of preparing them well, by clearing them, both inside and outside, from a fatty humour with which they are naturally impregnated, and which prevents the ink from flowing freely along the pens made with them. The Dutch employ hot cinders or ashes to attain this end; and their secret was preserved very carefully, but it at length transpired, and the process was then improved. In the improved method the barrel end of the quill is plunged for a few seconds in a sand-bath, heated to about 140° Fahr., and then rubbed strongly with a piece of flannel. After this it appears white and transparent. In another method the workman sits before a small stove fire, into which he thrusts the barrel of the quill for about a second. Immediately upon withdrawing it from the fire, he draws it under the edge of a large blunt edged knife, called a *hook* (shaped somewhat like a patten-maker's knife, and like it, having a fulcrum at one end, formed by a hook and staple, and a handle at the other end, by which pressure may be communicated), by which it is forcibly compressed against a block or plate of iron, heated to about 350° Fahr. By this process the barrel, which is rendered soft and elastic by the heat, is pressed flat, and stripped of its outer membrane, without danger of splitting. It springs back to its natural form, and the dressing is completed by scrubbing with a piece of rough dog-fish skin. The principal workman employed in this operation can pass 2000 quills through his hands in a day of ten hours. In a fourth method which is considered inferior as regards the quality of the quills for pen-making, although it makes them somewhat more pleasing to the eye, the quills are first stained yellow by steeping them for a night in a decoction of turmeric, then dried in warm sand, and subsequently scraped in the manner above described. Steaming for four hours has also been suggested as a good mode of dressing or preparing quills. By whatever process the external membrane is removed, that inside the quill remains, separated from it, and shrivelled up in the centre of the barrel, until it is cut open to convert it into a pen.

FEBRUARY, the second month of the year. Its name is derived from *februo*, to purify or cleanse. The Lupercalia were celebrated in this month. (Ovid, 'Fasti,' ii. l. 19, 31.) The Saxons called it *Sol-Monath*, because the sun's meridian altitude visibly increases in it.

February was not in the Calendar of Romulus. It was added to the year by Numa, who gave it the twelfth place in the Calendar. The Decemviri transferred it to the place in which it now stands. (Ovid, 'Fasti,' ii. l. 47.) Numa assigned twenty-eight days to it in order that the sum of the year might be an uneven number, according to a Pythagorean fancy. (Macrob. 'Saturnal.' li. i. c. 13.) In an ordinary year February has twenty-eight days; in bissextile, or leap-year, it has a twenty-ninth, or intercalary day, except once at the end of each period of four centuries.

FECIALES, in ancient Rome, were the messengers or heralds of war and peace; they belonged to the order of the priesthood, and their persons were held sacred even by enemies. When the Romans had or pretended to have grievances against another state, they sent one of the feciales, who clad in his solemn robes, entered the obnoxious territory or town, and in the presence of the assembled people, or of the magistrates and rulers of the country, stated the complaints of the Romans, and asked for reparation. A certain time, generally thirty days, was allowed for deliberation and for returning an answer, at the end of which the fecial herald came again, and if the answer was not satisfactory, he took to witness Jupiter and the other gods that he had religiously performed his duty, and that it was now the business of the Roman senate and people to decide upon the question. On his return to Rome he declared to the senate the result of his mission, and told them that they might now declare war if they thought proper. If war was decided upon, the fecial herald went again to the limits of the hostile state, and there, in presence of witnesses appealing to Jupiter and the other gods celestial and terrestrial, he protested against the injustice of that people and their obstinacy in refusing reparation, and declared that nothing now remained for Rome but to seek satisfaction by its own arms: he then threw a spear within the hostile boundaries, upon which war was considered as begun. When a treaty of peace or alliance was to be concluded, the presence of the feciales was likewise required, as with the Romans all political conventions partook of a religious character. The Etruscans and other ancient Italian nations had also their feciales. This institution had a beneficial effect, insomuch as it tended to humanise the system of warfare, and to prevent sudden and unexpected aggressions.

FECULA. [STARCH.]

FEDERATION. A federal union of sovereign states may be most easily conceived in the following manner :—

We will suppose that the sovereign power in any number of independent states is vested in some individual in those several states. These sovereign persons may agree respectively with each other and with all not to exercise certain functions of sovereignty in their several states, and to transfer these functions to be jointly exercised by the contracting sovereign persons. The consequence of such a compact will be that the contracting sovereign persons in their joint capacity will become sovereign in each state and in all the states. The several sovereign persons having for the time surrendered to the joint body certain powers incident to their several sovereignties are no longer severally sovereign in their several states. The powers surrendered to the joint body may be determined by written contract, the interpretation of which belongs to the joint body, yet in such a manner that there can be no valid interpretation unless the sovereign persons are unanimous; for if any number or majority could bind the rest, they might, by interpretation, deprive the several contracting persons of all the powers reserved to them by the contract. It follows also from the terms of the union, that any one party can withdraw from it at pleasure, and, as far as he is concerned, dissolve the union; for the essence of this union is the continuing consent of all.

This is the simplest possible form of a supreme federal government; one in which the contracting sovereign powers are individuals, and in which the sovereign persons in their aggregate capacity exercise the functions of sovereignty. Such a federation may never have existed, but any federation that does exist or can exist, however complicated it may seem, is reducible to these simple elements.

If the sovereign powers, instead of being in individuals, are in all the people of the respective states, the only difference will be that the functions of sovereignty, which in the first case we supposed to be exercised by the individual sovereigns in their joint capacity, must, in this case, be delegated to individual members of the sovereign body. The citizens of the several sovereign states must in the first instance of necessity delegate to some of their own body the proper authority for making the federal contract or constitution; and they must afterwards appoint persons out of their own body, in the mode prescribed by the federal contract, for executing the powers intrusted by the federal contract to persons so appointed. Thus the individuals who form the federal contract act therein severally as the agents of the sovereign states from which they receive their commission; and the individuals appointed to carry into effect the terms of the federal contract are the ministers and agents of that sovereign power which is composed of the several sovereign states, which again are composed of all the citizens. By whatever name of President, Senate, House of Representatives, or other name, the agents of the sovereign power are denominated, they are only the agents of those in whom the sovereign power resides.

When the sovereign power is so distributed, the question as to the interpretation of the federal contract may in practice be more difficult, but in principle it is the same. No one state can be bound by the interpretation of the rest, for if this were once allowed there would be no assignable limit to the encroachments of the states exercising sovereign power in their aggregate capacity. It is a clear consequence of the nature of the compact, whether the several sovereign powers are nations or individuals, that each contracting power must exercise its judgment on the interpretation of the instrument to which it is a party, and that no interpretation from which any power dissents can, consistently with the nature of the compact, bind that power.

In the case of complete dissent or disagreement by any one power, the contract is, by the very nature of its terms, at an end; for the contract being among sovereign powers, they cannot severally as such yield *obedience* to another sovereignty, which results from the aggregation of their several sovereign powers: their acts in their joint capacity must be acts of complete consent.

If the sovereign power in such a federal union has delegated the power of interpreting the written instrument of union to certain judiciary authorities, appointed under the federal compact for the purpose of carrying its provisions into effect, the several sovereign powers must still exercise, either by their legislatures or their judiciary authorities, their right to judge of the correctness of the interpretation, just as much as if the several sovereign persons, in the case first supposed, themselves exercised the functions of sovereignty in the supreme federal government.

What is commonly called the general government of the United States of North America is an example of a federation or federal government, or a supreme federal government. The contracting parties were sovereign states (the sovereignty in each state being in the citizens), which in their aggregate capacity formed a supreme federal government. The ministers for carrying into effect the federal government are the president and congress, and the judiciary of the United States. By the preamble to the constitution it is in fact declared that the "people of the United States" are the contracting parties.

The fifth article of the constitution provides that "The congress, whenever two-thirds of both houses shall deem it necessary, shall propose amendments to this constitution, or on the application of the legislatures of two-thirds of the several states, shall call a convention for proposing amendments, which, in either case, shall be valid to all intents and purposes, as part of this constitution, when ratified by the legislatures of three-fourths of the several states, or by conventions in three-fourths thereof, as the one or the other mode of ratification may be proposed by the congress; provided, &c., and that no state, without its consent, shall be deprived of its equal suffrage in the senate." From this article it is clear that the framers of the constitution did not fully comprehend the nature of the supreme federal government; for it is assumed by this article that the several states may be bound without their unanimous consent, which is contrary to conditions essentially implied by the nature of the union. This article involves also the inconsistency that the sovereign in any state may bind his successors: if the case of a federation of individual sovereign persons had been that to be provided for, the impossibility of the provision would have been apparent; but the impossibility equally exists when the contracting sovereign powers are respectively composed of many individuals, for the abiding consent is still the essence of the union that has been formed.

This is not the proper place to discuss the advantages and disadvantages of a supreme federal government, nor to examine into its stability. That it is necessarily deficient in one element of stability, namely, in there being a necessity for all the consenting parties to continue their consent, is evident: in this respect it is like a partnership for an indefinite period, which may at any time be dissolved by any one of the partners. Such a power, which is incident to the nature of the partnership, so far from being an objection to it, is a great advantage. So long as all the parties agree, they have the benefit of the union: when they cannot agree, they take instead of it the benefit of the separation.

It is also foreign from our purpose to consider what is the tendency, in a union like that of the United States, resulting from the powers placed in the hands of the president and congress by the states acting in their aggregate capacity. If such power were placed in such hands by sovereign persons originally severally sovereign in their respective states, as in the case first supposed, the vigilance of these persons in their aggregate capacity, though somewhat less than the vigilance of a single sovereign person, would probably prevent any undue assumptions of power on the part of those to whom they had delegated certain fixed powers. But the farther the several sovereigns, who in their aggregate capacity form this federation, are removed from those to whom they delegate certain powers, and the more numerous are the individuals in whom this aggregate sovereignty resides, the greater are the facilities and means offered to, and consequently the greater is the tendency in, their ministers and agents practically to increase those powers with which they may have been intrusted. In their capacity of ministers and agents, having patronage at their command and the administration of the revenue, such agents may gradually acquire the power of influencing the election of their successors, when their own term of office is expired, and may thus imperceptibly, while in name servants, become in fact masters. That there is such a tendency to degenerate from its primitive form in all social organisation, as there is in all organised bodies to be resolved into their elements, seems no sufficient reason for not forming such union and deriving from it all the advantages which under given conditions it may for an indefinite time bestow on all the members of such federation.

Federations of a kind existed in ancient times, such as that of the Ionian States of Asia, which assembled at the Panionium at certain times (Herodotus, i. 142); the Achæan confederation; the Ætolian confederation; and the Lycian confederation, which is described by Strabo (p. 664). The Roman system of fœderate states (*civitates fœderatæ*) is another instance of a kind of confederation; but it was of a peculiar kind, for Rome was neither absolutely sovereign over these states nor yet associated with them in a federation, as now understood. The relationship between Rome and the federate states rather resembled the relation of sovereign and subject than any other, though it was not precisely that.

A supreme federal government, or a composite state, is distinguished by Austin ('Province of Jurisprudence Determined') from a system of confederated states: in the latter, "each of the several societies is an independent political society, and each of their several governments is properly sovereign or supreme." It is easy to conceive a number of sovereign powers, such as the German states, assembling and passing resolutions which concern all the members of the confederacy, and yet leaving these resolutions to be enforced in each state by its own sovereign power. Such a union, therefore, differs essentially from a supreme federal government, which enforces its commands in each and all the states. As to the existence of a written constitution, as it is called, in the one case, and a mere compact in the other, that makes no essential difference; for the federal constitution, as we have shown, is merely articles of agreement, which only derive their efficacy from the continued assent of all the members that contribute in their aggregate capacity to form the sovereign power in such federation.

As to a system of confederated states, Austin adds, "I believe that the German Confederation, which has succeeded to the ancient empire, is merely a system of confederated states. I believe that the present diet is merely an assembly of ambassadors from several confederated but severally independent governments; that the resolutions of the diet are merely articles of agreement which each of the confederated governments spontaneously adopts; and that they owe their legal effect, in each of the compacted communities, to laws and commands which are fashioned upon them by its own immediate chief. I also believe that the Swiss Confederation was and is of the same nature. If, in the case of the German or of the Swiss Confederation, the body of confederated governments enforces its own resolutions, those confederated governments are one composite state, rather than a system of confederated states. The body of confederated governments is properly sovereign; and to that aggregate and sovereign body each of its constituent members is properly in a state of subjection."

FEE-FARM RENT. [RENT.]

FEE-SIMPLE. [ESTATE.]

FEE-TAIL. [ESTATE.]

FEELING. [TOUCH.]

FEES, certain sums of money claimed as their perquisite by official persons under the authority of various Acts of Parliament, and by prescription. The right to fees, as well as the amount payable in most cases connected with the administration of justice, has been regulated by several recent statutes.

Officers demanding improper fees are guilty of extortion. [EXTORTION.]

The rewards paid to barristers and physicians, attorneys and surgeons, for their several services, are called fees, which may be recovered by the three last-named by action. Barristers cannot recover their fees by any legal proceeding; nor can physicians, if they are members of a college of physicians which has enacted a bye-law to that effect. [COUNSEL; PHYSICIAN.]

FEHM GERICHTE, FEMGERICHTE, or VEHM GERICHTE, the celebrated courts of justice of Westphalia, which have been, on very slender authority, said to be the relic of an institution of Charlemagne, but which certainly flourished and possessed most enormous power and influence during the 13th and 14th centuries. It was chiefly confined to what was then known as Westphalia, which included nearly all the countries between the Rhine and the Weser, and extended from the mountains of Hesse on the south to Friesland on the north; and this district bore the mystic name of the *red earth* in the records of the time, though the exact derivation or meaning of the term is uncertain. It would seem that, whatever earlier institutions it may have been founded upon, the tribunal was first organised when, after the deposition and outlawry of the emperor Henry the Lion, the authority of the laws, both civil and ecclesiastical, gave way to force, which, in the hands of ignorance and rapacity, threatened society with dissolution. In order to check the audacity of those who, relying upon their power, thought themselves above the reach of the law, and for the protection of the defenceless and innocent, a secret tribunal was formed, called the sacred Fehme, or Fehm Gericht.

These tribunals arose from the like causes which formed the trade-guilds in towns, and the confederacy of the Hanse Towns, namely, the necessity of individuals following peaceful professions defending themselves by unions against the spoliation and tyranny exercised by the feudal nobility, and which neither the law nor the emperor was able to repress, nor, except in rare cases, to punish. When these confederations became sufficiently powerful to defend themselves, the neighbouring nobility were frequently desirous of becoming members of the community, in order that they might in some measure guide what they could no longer resist. It was in fact an early development of public opinion developed in forms peculiar to the period; and the sentences of the Fehm Gerichte itself, except that the institution was permanent, resembled in some of its features those of the Lynch-law in the back settlements of the United States of America. There was usually no concealment, the trial was held commonly in the open air, in the presence of an audience; and it was only on the conviction of an offender who failed to appear that his death was effected by the means which added so much mystery and terror to the judgments of the courts.

By the constitution of the tribunal, the Emperor of Germany was the nominal head, who was usually made a member of the Fehm on his coronation at Aachen: but very early the archbishop of Cologne was made the imperial lieutenant in Westphalia; and indeed it is stated that archbishop Engelbert was, in 1179, the first Freygraf. Under the archbishop were the tribunal lords (Stuhlherren), to each of whom a particular district was assigned, beyond which he had no jurisdiction. The Stuhlherr either presided in the courts himself or deputed a count (Freygraf) to take his place; for the country was divided into counties (Grafschaften), and every county had at least one Freygraf, who took an oath to judge truly and justly, and to be obedient to the emperor and his lieutenant. Next to the counts were the assessors or Schöppen, who formed the bulk of the society. These were nominated by the count, with the approval of the Stuhlherr, after having been recommended by two persons, already members of the tribunal, who vouched for the fitness of the candidate. The candidate was required to have been born in marriage, of free parents, to be a Christian, to be neither excommunicated nor outlawed, not to be involved in any process before the tribunal, not to belong to any spiritual order, and at first to have been a native of Westphalia; but latterly strangers were admitted. Kneeling bareheaded before the assembly, with his thumb and forefinger on a naked sword and a halter, he swore—

"I promise, on the holy marriage, that I will, from henceforth, aid, keep, and conceal the holy Fehms, from wife and child, from father and mother, from sister and brother, from fire and wind, from all that the sun shines on and the rain wets, from all that is between sky and ground, especially from the man who knows the law; and will bring before this free tribunal, under which I sit, all that belongs to the secret jurisdiction of the emperor, whether I know it to be true myself, or have heard it from trustworthy people, whatever requires correction or punishment, whatever is Fehm-free (that is, a crime committed in the county), that it may be judged, or, with the consent of the accuser, be put off in grace; and will not cease so to do, for love or for fear, for gold or for silver, or for precious stones; and will strengthen this tribunal and jurisdiction with all my five senses and power; and that I do not take on me this office for any other cause than for the sake of right and justice; moreover, that I will ever further and honour this free tribunal more than any other free tribunals; and what I thus promise will I steadfastly and firmly keep, so help me God and his Holy Gospel."

As soon as the neophyte had pronounced the oath, he was informed that the object of the association was to uphold peace, virtue, and honour against the open or concealed enemies of the law; and as the interest of the order required that the schoppen of the different counties and principalities should be known to each other, they had adopted a sign consisting of four letters, S.S.G.G., the signification of which is still involved in mystery. The neophyte was further presented with a rope, which he was obliged to carry in his left sleeve, and also a dagger, on which the four above-mentioned letters were engraved, together with other symbols. Moreover he was charged with the duty of accusing before the secret tribunal all those who could not be successfully prosecuted before the ordinary courts, and of executing capital punishment whenever required by the society to perform this duty.

The mode of proceeding against the accused was as follows: If the author of a crime absconded, or his residence was unknown, the schöppe was required to write four summonses, and post them on a cross road; but if the residence was known, the schöppe came at night, and nailed the summons with four nails, folded as a letter, containing an imperial farthing, on the man's door. He then rang the bell, and told the porter that he had brought a letter from the sacred tribunal for his master. The initiated could go through the country unimpeded, on foot or on horseback, for none was so daring as to stay or injure him. The summons required the accused to appear at a certain hour at the appointed spot, within a fortnight after its delivery, to answer for his base and criminal conduct before the sacred tribunal, or otherwise clear himself of the accusation; at the same time threatening to proceed against him for contempt in case of non-appearance. If the accused attended the summons, the schöppe who brought the accusation was called upon by the Freygraf to state all that he and his witnesses knew relating to the charge, after which the accused and his witnesses were heard. The judges assembled on a Tuesday in the open air. The count presided, and before him on the table lay a naked sword and a withy halter. On his right and left stood the clerks of the court, the assessors, and the audience, all bareheaded, their hands uncovered, and unarmed, signifying that they would cover no right with unright, that they would do nothing underhand, and that they were at peace with the emperor and the law. They wore short mantles to show that as the cloak covers the body so should their love cover justice. Each party was entitled to produce compurgators, and the verdict was left to the assessors. An appeal, however, lay, if claimed before the court broke up, to the Secret Closed Tribunal of the Imperial Chambers, which usually held its sittings at Dortmund. These proceedings were for the uninitiated; for the initiated it was sufficient that the accused, laying his two forefingers on the naked sword, swore he was innocent; but one of the initiated convicted of revealing the secrets of the tribunal was immediately hung. When the sentence was pronounced, the execution of which, in case of capital punishment, was intrusted to all the members of the order, the condemned, if present, was at once executed; if he had not appeared, the schöppen were set in pursuit of him. Whenever three schöppen (for that was the number necessary for an ordinary execution) met the person condemned, they seized him, and with one of the ropes which they carried in their sleeves, hung him on the next tree, fixing a dagger in the trunk to denote that the deceased was killed by the holy tribunal. When such an event occurred, no court of law dared to take notice of the affair; every man's tongue was struck silent, for fear of incurring the vengeance of this terrible body. This punishment, however, was seldom inflicted upon those who readily appeared; in such cases the judges were satisfied with causing the defender to redress the wrong that he had inflicted. But if the accused failed to attend the summons, which was repeated three times, judgment passed by default, and the accused was declared an outlaw. Every schöppe, though he were the father or son of the criminal, was in duty bound to put him to death by the rope, the dagger, the sword, or even poison, and to revenge any insult offered to the tribunal upon man, woman, or child, noble or plebeian, freeborn or slave, house or farm, monastery or nunnery, that dared to shelter him.

The power of this tribunal was greater than that of the Holy Inquisition; it struck terror into all Germany, and especially in Westphalia, where it originated. Princes and nobles were anxious to enter into this order either for protection against their enemies, or to avoid the jurisdiction of a tribunal the power of which they were unable to withstand. Towards the end of the 15th century, the German empire having acquired more political consistency, and the objects for which this tribunal was instituted having ceased to exist, it gradually lost its power, without being abolished by any legislative enactment. Some traces of the revival of this tribunal appear in the 17th century, but its efforts to regain its former importance were checked by the public authorities. It sunk at length into utter insignificance; and a remnant of it which continued to act as a kind of society for the suppression of vice was abolished in Westphalia by order of Jerome Bonaparte in the year 1811. The members of the order maintained that they were the true and genuine possessors of the secrets intrusted to the Fehm by Charlemagne, but no one would or could explain the signification of the mystical S.S.G.G. Goethe has given a graphic picture of the working of this tribunal in his historical drama 'Göetz von Berlichingen;' and Scott in his 'Anne of Geierstein,' has described the proceedings of the tribunal: but neither have confined themselves to the historical facts, and the last has wandered widely. The best historical accounts of its organisation are by Bork, 'Geschichte der Westphalischen Vehmgerichte,' Bremen, 1815; Paul Wigand, 'Das Femgericht Westfalens,' Hamm., 1827; and Usener, 'Die Frei und heimlichen Gerichte Westphalens,' Frankfurt, 1832.

FEIGNED DISEASES. There are few subjects attended with more difficulty than the detection of feigned diseases, especially when they are the result of a system which permits of a constant refinement of the deceit by practice. This has been especially the case in France, where the object has been to escape the conscription. Foderé has observed, "that it was brought to such a perfection as to render it as difficult to detect a feigned disease as to cure a real one." The motives which usually lead to this practice are—1, A release from obligation. This is frequently the case in the army and navy, where the men will pretend to be ill to escape duty or to gain their discharge. In this form it has got the name of *Malingering.* Beggars, too, often feign illness when they are offered work, preferring the easy task of soliciting charity to the labour of an occupation. 2, The hope of gain. This motive comes into operation where the object is to obtain relief from the parish, to impose upon the benevolence of private persons, to procure the allowances of benefit societies, clubs, &c., to get admitted into an hospital, or to obtain compensation for some pretended injury. 3, To procure release from confinement or an exemption from punishment. This motive is a source of deceit with boys and girls at school, persons committed to prison, &c. To these may be added the love of exciting the sympathy or gaining the attention of others, where no hope or need of gain exists. This motive acts in all classes of society, and leads individuals of otherwise the highest moral character to imitate all forms of disease. It is observed most frequently in young and unmarried females, and is frequently carried to the extent of feigning diseases for which capital operations are required; and instances are not wanting where surgeons (not much however to their credit) have removed legs, breasts, and arms at the solicitation of such patients.

There is no natural limit to diseases which may be feigned; but some being much more easily imitated than others, and less easily detected, are most frequently assumed. Feigned diseases may be divided into, 1, those which are obvious to the senses; 2, those depending upon the description of the impostor, and 3, those of a complicated nature, presenting symptoms of both kinds. Amongst diseases obvious to the senses are an increased or diminished size of parts, wounds, malformations, ulcers, discharges, spasmodic and paralytic affections. A favourite mode of increasing the size of parts, and producing tumours, is by injecting air beneath the cellular membrane. In this way such diseases as dropsy, local and general, hernia, hydrocele, varicose veins, elephantiasis, œdema of the extremities, may be simulated. Pressure also, by means of ligatures, &c. on the veins, will produce swellings of parts of the body. Swellings also of the joints, so as to resemble white swellings, are produced by the application of various acrid plants, as the ranunculus acris and sceleratus to the part. Polypi, hydatids, malignant tumours, and hæmorrhoids, are imitated by affixing in some manner the intestines and other viscera of animals to the parts of the body in which these diseases occur. Cancer has been imitated by a cow's spleen, and by a sponge moistened with milk fixed under the arm-pit. The various malformations of the body are feigned by obstinate and long-continued flexion of the part, aided by inaction and the use of tight bandages. Sometimes these contractions are accompanied by a wound, in order to prove that they have been effected by a burn. Many means have been proposed for detecting this class of impositions, such as compressing with a tourniquet the nerves that supply the contracted muscles; applying a wet bandage tightly round the limb, so that when it becomes dry it may overcome the contraction; moving the contracted limb during natural sleep or that produced by narcotics; or making extension whilst the person is under the influence of an emetic, or when his attention is directed to other objects; recommending the coast of Africa, or some other disagreeable thing, as a cure. Wounds and sores are produced in a variety of ways. Wounds, when self-inflicted, will always be in positions where persons can get at the spot where they exist, with their own hands. Accomplices are however sometimes engaged even in this. Ulcers are among the most common of feigned diseases. They are produced by red-hot iron, by caustics, as corrosive acids and alkalies, and the juices of various plants, as of the ranunculus acris and sceleratus, the spurge-laurel, the euphorbium, arum maculatum, and juniper. Where persons are suspected of keeping up ulcers in their legs by irritants, the placing their legs in a box and locking them up will allow the ulcers to heal. The various forms of cutaneous disease are produced by the application of irritants to the skin, as pounded garlic, euphorbium, cantharides, gunpowder, nitric acid, bay salt, &c. The discoloration of jaundice is imitated by various dyes, as well as the appearance of bruises. Ophthalmia is a disease often feigned, and is commonly produced by the application of irritants, as snuff, pepper, tobacco, blue vitriol, salt, alum, &c. The progress of the inflammation in these cases is usually more rapid than in the idiopathic form. It is mostly also confined to one eye, for obvious reasons; and when occurring in the army it may be suspected, if epidemic, when it only comes on in privates and non-commissioned officers. Diseased discharges are often simulated. Vomiting is effected by pressing on the pit of the stomach, by swallowing air, by strong and sudden action of the abdominal muscles, by tickling the fauces, and the use of emetics. Diarrhœa and dysentery are produced by taking drastic purgatives. Fragments of brick, slate, small pebbles, pieces of quartz, and flint, have been introduced into the urethra, to bear out the alleged existence of urinary calculus. Hæmaturia has been simulated by tinging the urine with various colouring matters, and the disease has really been brought on by the taking of savin, cantharides, and turpentine. Spitting of blood is a favourite assumed disease. It is simulated by placing a sponge in the mouth filled with bullock's blood, by cutting the mouth and gums, and by sucking blood from other parts of the body. A vomiting of urine and fæces have taken place by the stealthy introduction of the contents of the bladder and rectum into the stomach.

The spasmodic diseases to which the system is subject have been imitated with great success, and none more so than epilepsy. It has for its peculiar recommendation, that the person who is subject to it may be well at intervals and assume the attacks when it best suits him. The best criterion of imposition is the want of the total insensibility which characterises the true fits. In the feigned disease the application of stimulants will seldom fail to elicit indications of sensibility. Hartshorn or burning sulphur may be introduced under the nose: alcohol and turpentine may be dropped into the eye, and mustard or common salt placed in the mouth. Pricking the skin with sharp-pointed instruments has also been recommended. This however is frequently resisted. Dr. Guy recommends "flecking" the feet with a wet towel. He says he has by this means aroused a patient from a mesmeric slumber when all other mechanical stimulants and cold affusions had failed. Convulsions are often imitated; but where they are fictitious they cannot be sustained for any length of time without great exhaustion. Chorea is also often imitated. Electricity and cold affusions are the best remedies for this disease, and are likely to be effectual in the case of impostors. Hysteria, catalepsy, tetanus, hydrophobia, some forms of tonic spasm, stammering, strabismus, and difficulty of swallowing, are other diseases of the nervous system which are often imitated. Paralytic affections are also frequently simulated. The treatment resorted to for the cure of these diseases, when natural, would be found a trying ordeal for most impostors. Cases however are related in which impostors have resisted the most active treatment; and a case of simulated lethargy is on record, in which an individual resisted with only a single groan the operation of trephining.

Another class of feigned diseases are those which depend chiefly upon the description given by the impostor. These are all embraced in increased and diminished sensations. Increased pain of one or many organs is commonly feigned. It is easily assumed but not easily detected, as many pains, such as that of tic douloureux, come on in an apparently healthy state of the system; and many pains of a severe character are dependent on exceedingly obscure causes. There are no rules which can be laid down for the detection of simulated pain; and it is only those who have extensively observed the effects of real pain on the system, that can readily distinguish that which is pretended. Of diminished sensations, blindness, and deafness are those most frequently feigned. Amaurosis may be really produced for a time by the application of belladonna, henbane, spurge laurel, and tobacco; but under these circumstances it disappears when the impostor is carefully watched. Deafness is often assumed, but it may be detected by unexpectedly or sharply calling out the name of the individual, by calling him by name when asleep, or letting a piece of money fall close to him. Dumbness has been successfully feigned, and cases are recorded which resisted every attempt at discovery. It may be frequently detected by giving the person a sudden and unexpected knock, or a prick with a pin.

Sometimes general diseases are assumed, embracing a collection of symptoms. Of these, the most frequently assumed are fever, ague, rheumatism, phthisis, asthma, dyspepsia, jaundice, inflammations of the bowels, stomach, and kidneys. These feigned diseases are only to be detected by a knowledge of the real diseases, when a correct diagnosis is not often difficult. Of diseases involving complicated symptoms, that of unsoundness of mind is most frequently and most successfully feigned. The success however does not depend so much on the ease with which the symptoms of true insanity are imitated, as upon the ignorance that prevails of the distinguishing characters of real insanity. When these are once known an impostor may be easily detected. The most frequent form of assumed madness is general mania. In addition to the characters of the true disease, special tests have been proposed, such as the use of the whirling chair, and "repeating to the suspected person a series of ideas recently uttered, when the real maniac will introduce new ideas; the impostor, on the contrary, will deem it expedient to repeat the same words." (Guy.)

The following general rules for detecting feigned diseases have been given by Zacchias :—

1. The first is, that the physician must in all suspected cases inquire of the relatives and friends of the suspected individual what are his physical and moral habits. He must ascertain the state of his affairs, and inquire what may possibly be the motive for feigning disease, particularly whether he is not in immediate danger of some punishment from which this sickness may excuse him.

2. Compare the disease under examination with the causes capable of producing it—such as the age, temperament, and mode of life of the patient. Thus artifice might be suspected if a person in high health and correct in his diet should suddenly fall into dropsy or cachexia; and again if insanity should suddenly supervene without any of its premonitory symptoms. It is contrary to experience to find such diseases occur without some previous indications.

3. The third rule is derived from the aversion of persons feigning disease to take proper remedies. This indeed will occur in real sickness, but it rarely happens when severe pain is present. Anything that promises relief is generally acceptable in such cases; those on the contrary who feign delay the use of means.

4. Particular attention should be paid to the symptoms present, and whether they necessarily belong to the disease. An expert physician may thus cause a patient to fall into contradiction, and lead him to a statement which is incompatible with the nature of the complaint. To effect this it is necessary to visit him frequently and unexpectedly.

5. The last direction is to follow the course of the complaint and attend to the circumstances which successively occur.

(Beck, *Medical Jurisprudence*; Thomson, A. T., *Lectures on Medical Jurisprudence*; Guy, W. A., *Principles of Forensic Medicine*.)

FELLOWSHIP, in books of arithmetic, the rule by which profit or loss is divided among those who are to bear it, in proportion to their investments or interests in the transaction. It is usual to divide this rule into two parts, of which the first supposes all the investments to have been made for the same time, and the second supposes the partners to have employed their money during different times. One simple case of each will be sufficient.

Question 1. A, B, and C embarked 10l., 9l., and 8l. in a venture which yielded 30l. of profit. How much belongs to each?

If 10 + 9 + 8, or 27 adventurers embarked 1l. each, it is clear that each of them should have the 27th part of 30l. Let 10 of them assign their shares to A, 9 to B, and 8 to C, and we have the case in question. That is, A should have 10-27ths, B 9-27ths, and C 8-27ths of the whole profit.

Question 2. A profit of 30l. was realised by A embarking 10l. for two months, B embarking 9l. for three months, and C embarking 8l. for four months. How much ought each to gain?

Here the 1l. of A and the 1l. of B are differently circumstanced: the second was employed half as long again as the first, and consequently should gain half as much again. Now let *one pound sterling employed during one month* be called a share: then A invested 20 shares, B 27 shares, and C 32 shares. Hence, as before, 20 + 27 + 32 being 79, A should have 20-79ths, B should have 27-79ths, and C 32-79ths of the gain.

The first is a rule of very frequent occurrence; but the second is rare, for it seldom happens that money is withdrawn from an undertaking, except upon some specific agreement. But the modern practice of dividing an enterprise into shares of equal amount, and never subdividing a share, reduces all questions of fellowship to simple division. But, as often happens, a name has got into the wrong place. The result which division gives to A, instead of being called his *quotient*, is called his *dividend*.

FELLOWSHIP (in a college) is an establishment in the college entitling the holder to a share in its revenues. The fellows are a part of the corporation. [College.] Fellowships are either original, that is, part of the foundation or scheme of the original founder; or ingrafted, that is, endowed by subsequent benefactors of a college already established. Where the number of fellows is limited by the original foundation, new fellows cannot be made members of the corporate body without a new incorporation. If the number is not limited by the charter, it seems that the corporation may admit new fellows as members, who will be subject to the statutes of the original foundation in all respects. Graduates of each several college are in general only eligible to fill a vacant fellowship in the establishment to which they belong after having been elected to scholarships on the foundation, awarded at examinations held by the master and fellows in being. But in some cases special rules which control the election prevail, as where the fellow must be of the blood of the founder, or where he must be a native of a particular county, &c., and in some few cases fellowships are open to the graduates of several colleges, or even the whole university. In Downing College graduates of both universities are eligible. These rules are prescribed by the founder, modified in some cases by the bye-laws of the several colleges. Some few fellowships may be held by laymen, but in general they can be retained only by persons already in holy orders, or who are ordained within a specified time. Fellowships are of unequal value, varying from 30l. and less to 250l. a year and upwards, the senior fellowships in those colleges where there is any such distinction between the fellows being the most lucrative; but all confer upon their holders the right to apartments in the college, for which in some instances a small annual sum is charged as rent, and certain money privileges as to commons or meals. They are in general tenable for life, unless the holder marries, or inherits estates which afford a larger revenue, or accepts one of the livings belonging to the college which cannot be held with a fellowship; but in the new statutes now under discussion, the commissioners for the University of Cambridge propose to limit the tenure in some of the colleges (at the same time removing the restriction against celibacy). These livings are conferred upon the fellows, who in general have the option of taking them in order of seniority, though in some colleges the holders of particular offices have priority of choice, as for instance in Trinity College, Cambridge, where the vice-master has such right by a bye-law of the college.

The whole subject of fellowships in the different colleges of the University of Cambridge is at the present time, January, 1860, in a transition state; the commissioners above-mentioned being engaged in the duty of revising and altering the old statutes, in which revision very important changes both as to the tenure of, and mode of election to, fellowships, and the position of the fellows themselves, are contemplated.

FELO-DE-SE (a felon of himself) is a person who, being of sound mind and of the age of discretion, deliberately causes his own death; and also, in some cases, where one maliciously attempts to kill another, and, in pursuance of such attempt, unwillingly kills himself, he is adjudged a felo-de-se. (1 Hawk. P. C. c. 27, § 4.) When the deceased is found by the coroner a felo-de-se, all his chattels, real and personal, are forfeited to the crown, though they are usually restored upon payment of moderate fees; and therefore a will made by him is void as to his personal estate, though not as to his real estate, nor is his wife barred of her dower. Formerly he was buried in the highway with a stake driven through his body. These laws, so highly repugnant to the feelings of humanity, being a punishment to the surviving relatives of the deceased, in addition to the general impression that no man in his sound sense ever does commit suicide, caused juries in general to find that the deceased was not of sound mind; and by the Act 4 Geo. IV. c. 52, the legislature has so far yielded to the popular and herein the better opinion, as to abolish the former ignominious mode of burial, and to provide that a felo-de-se shall be privately interred at night in the burial-ground in which his remains might by law have been interred if the verdict of felo-de-se had not been found against him.

FELONY, in the general acceptation of the English law, comprises every species of crime which occasioned at common law the forfeiture of lands or goods, or both, and to which a capital or other punishment might be superadded, according to the degree of guilt. Various derivations of the word have been suggested. Sir Henry Spelman supposes that it may have come from the Teutonic or German "fee" (fief or feud) and "lon" (price or value), or from the Saxon "feelen" (to fall or offend). Capital punishment by no means enters into the true idea and definition of felony; but the common notion of felony has been so generally connected with that of capital punishment, that law-writers have found it difficult to separate them: indeed, this notion acquired such force, that if a statute made any new offence felony, the law implied that it should be punished with death. The number of offences, however, to which this punishment is affixed by the law of England is now very small: and several statutes were passed early in the present reign (1 Vict.) founded upon the principle that the punishment of death should only be inflicted for crimes accompanied with violence. Thus c. 84 substituted the punishment of transportation for that of death in those cases where the latter might still be inflicted for forgery; c. 85 materially lessened the severity of the punishment of offences against the person; c. 86 enacted that burglary unaccompanied with violence shall no longer be punished capitally, and provided that, so far as the offence of burglary is concerned, the night should be considered to commence at nine in the evening and to conclude at six in the morning; c. 87 mitigated the punishment attending the crimes of robbery and stealing from the person; c. 88 rendered piracy punishable with death only when murder was attempted; c. 89 regulated the punishment for the crime of arson; c. 90 mitigated the punishment of transportation for life in certain cases; and c. 91 abolished the punishment of death in the cases there specified. The principle of amelioration was carried still further four years later by the stat. 4 & 5 Vict. c. 56, abolishing capital punishment for embezzlement by servants of the Bank of England, offences under the Stamp Act, riotous demolition of churches, houses, &c., and also for rape. Great numbers of offences were formerly liable to this severe punishment; and it must seem strange to persons who do not observe the extreme difficulty with which old established customs and prejudices, however ill founded, are subverted, that this system should so long and so obstinately have withstood the most convincing arguments and conclusive statistical evidence. It is impossible, within the limits of this article, to enumerate the crimes which the law considers to be felonies; and the more so, as the word felony has long been used to signify the degree of crime rather than the penal consequences. It may be sufficient, therefore, to state generally, that murder, manslaughter, felo-de-se, robbery, arson, burglary, some offences against the coin, &c., are considered and classed as felonies; and (the distinction between grand and petit larceny no longer existing) every larceny is a felony.

Besides the special punishment affixed to his crime by the law, a felon upon conviction forfeited the rents and profits of his lands of inheritance during his life to the king (which are now usually compounded for), and also all his goods and chattels absolutely; and as attainder of felony caused corruption of blood, his lands, except of gavelkind tenure, escheated to the lord of the fee. This last consequence, however, was taken away by stat. 54 Geo. III. c. 145, which enacted that, except for treason or murder, corruption of blood should not follow attainder; and as difficulties might sometimes occur in tracing descent through an ancestor who had been attainted, it was, by the 3 & 4 Will. IV. c. 106, § 10, enacted that descent may be traced through any person who shall have been attainted before such descent shall have taken place. [ESCHEAT; FORFEITURE.]

In connection with this subject, it may be interesting to refer to the distinction formerly taken between felony with and without benefit of clergy, as explained in the article BENEFIT OF CLERGY.

FELT; FELTING. Under HAT MANUFACTURE will be found a description of that peculiar process whereby woollen and fur fibres are felted into a material suitable for hats; but woollen fibres are also sometimes combined by the felting instead of the weaving process for carpets and various kinds of cloth. Among other manufacturing firms for the purpose, there is the 'Patent Felted Woollen cloth Company;' by whom is made felt carpets, embossed and printed felt table-covers, felt polishing cloth for plate and other purposes, felt for veterinary purposes, felt waistcoatings, felt coach-cloths and railway-carriage-linings, upholsterers' felt, and felt for pianofortes.

A material called *Asphalted Roofing Felt* has come rather extensively into use. The two principal kinds are Croggon's and McNeill's. The qualities of this material are imperviousness to rain and snow, non-conductibility of heat, elasticity, lightness, durability, economy, and easy application. The felt is used for roofing buildings; for lining granaries and stores; for protecting ceilings from damp; for lining the insides or outsides of wooden buildings; for covering conservatories and garden-frames; for thatching corn and hay ricks; and for many other purposes. This felt is sold in large sheets at the rate of about a penny per square foot. Another kind, called Inodorous Felt, is saturated with waterproof material free from the smell of the ordinary felt, and is used to prevent wall-paper from being injured by damp. There is also a patent Felted Sheathing, for covering ships' bottoms; it is a felted mixture of hair and vegetable fibre, not intended as a substitute for copper sheathing, but to be used as a layer beneath it. Another variety, the Non-conducting Felt, is used as a covering for boilers and steam-pipes, on account of its power of confining the heat within the vessel enclosed by it; it is used for fixed, locomotive, and marine steam-engines, and in breweries and distilleries: it is said also to be a good protective of water pipes from frost. An Asphalted Felt is made in long pieces, 32 inches wide by about 30 yards long, and is sold in any smaller or larger quantities. The fibrous material of which it is formed is saturated with asphalte or bitumen. Some of the sheds and other buildings at Devonport and Woolwich Dock Yards, the Isle of Portland, and elsewhere, have been covered with this material; but its inflammability is a disadvantage.

For all the above and for other kinds of uses, new felted materials have been patented within the last few years. Williams's patent for felting wool or fur or both into cloth, taken out in 1840, was extended for a further period in 1854, on the ground that the process, although involving a heavy expenditure, had not yet yielded much profit. Parker's felt, patented in 1851, is made in a peculiar way. The fibres of wool, fur, or hair, are first made into a batt or soft sheet by the action of carding and doffing engines; this batt is wound on a roller and conveyed to the felting machine. There are two strata or beds of bars of wood, laid crosswise on straps or belts; the beds are horizontal, and a little distance apart; the batt of fibres is brought between them; and all the bars of the upper bed, having a reciprocating vertical movement, felt the fibres while travelling onward. The roller and the two beds dip in water, to facilitate the process. In reference to the felt for retaining the heat of steam-boilers, we may state that a new mode of procedure was introduced by Mr. Garnett in 1858. The felt is here composed entirely of waste woollen refuse from paper-mills, converted to coarse pulp in the ordinary rag engines; it is put upon the steam boiler in a wet or pulpy state, and is felted or matted together by being beaten with pieces of flat wood. When dry, it becomes one solid piece. As a proof of its excellent qualities as a non-conductor of heat, it is asserted that on a boiler working at 50 or 60 tons pressure, candles may be laid on the felt for weeks together, without melting. The felt may at any time be taken off and replaced, by steeping in hot water till softened. So far as concerns the manufacture of felted cloth for garments, America appears to have made a greater advance than England. Mr. Whitworth, the eminent machinist, in reporting on the machines displayed at the Great Exhibition in New York in 1853, had occasion to notice the Bay State Mills at Lawrence, nine miles from Lowell, and twenty-six from Boston. This is one of the largest woollen mills in the world, employing more than 2000 hands. He said:—"The whole waste from the mills is worked up in the manufacture of felted cloth. The felt-making machine employs but a small space. A sliver of wool is taken from the carding machine and passed between two endless cloths; these carry it over a narrow steam-box, where it is steamed. It is then passed under a vibrating pressing-plate, which operation causes the fibres to curl and interlace with each other, and so form a cloth." The cloth thus made is of fair quality in fineness and elasticity. A new and useful fabric made in that establishment is felted lining-cloth, composed of a small quantity of wool felted upon gauze; the gauze forms a back to the felt; and the substance obtained by this means is much thicker than the small quantity of material employed would seem to denote. The gauze surface is hidden when the lining is applied to a garment, and the felt is quite strong enough for the purpose in view. Some of the carpet and cloth felt made at these mills is printed by block-work; and in a few instances cloth for coatings is printed of two different colours on the two surfaces.

FEME-SOLE. [WIFE.]

FEMININE. [GENDER.]

FENCES are necessary wherever cattle are depastured and properties divided; and according as they are intended to prevent men or cattle from trespassing over them, they are formed of various materials and dimensions.

When a park is enclosed to keep in deer or game, the best fence is a stone or brick wall, well built with lime-mortar; but as this is expensive where stone and lime are not at hand, the common *park-paling* is more frequently met with. This is composed of posts and rails of oak mortised and pinned together, and split pales of the same material nailed upon these in an upright position. The pales are split out of the trunks of oaks, where there are no branches or knots, when the sap is still in them. They are about half an inch thick, and with feather edges, that is, diminishing in thickness from one side to the other: their usual width is five inches. When they are nailed on the rails, which are usually of a triangular form, the thickest edge of one pale is nailed over the thinner edge of the preceding, forming thus a very close fence. Every alternate pale is placed three or four inches higher than its neighbour, which gives the top of the fence a castellated form. This is not done merely for appearance; but it makes it more difficult to climb over, and the deer are not so apt to leap at it as if the top were a straight line. The distance between the posts is usually nine feet; and the three rails with the pales nailed on them is called a panel, and may be conveniently moved at once when any alteration in the fence is required. A whole fence may be moved at a small expense, merely by digging out the posts, and placing them elsewhere. The panels come in regularly, and are pinned into the old mortices in the posts. Sometimes the pales are nailed at a distance from each other, which makes the *open-paled fence*, and the pales are then generally cut to a point at top. This fence is peculiar to Great Britain and Ireland, and is very seldom found on the Continent.

In the Jura and the Alps, where wood abounds, a rough fence is frequently made with strong split pieces of wood, which are fixed obliquely in the ground and supported at the upper end by two others placed in the form of a cross. It is not a very strong fence, but it is sufficient to prevent the cows from straying, for unless a bull with his horns makes a gap in it, they will not attempt to pass it.

In wild mountain pastures in Scotland and Ireland, it is usual to separate the properties of different individuals or that of parishes by rough stone walls put together without any mortar. The materials are generally at hand, and a rough and efficient fence is made without much labour.

Some of these walls are built with considerable skill and are very durable; especially if the stone is of a nature to split with a flat surface, in which case a dry wall may be built which has all the appearance of one built with mortar. Sometimes a layer of mortar is laid on the stones at a little distance from the ground, and another near the top. The coping is usually made of flat stones, which are sometimes placed on edge in a direction across the wall, and wedged together along the top of it or set in mortar, forming a very rough coping, which it is not easy to get over.

Where stones are not at hand, or less trouble is taken, a high bank of earth faced with sods of grass is substituted for a wall. This is not so durable and is more easily surmounted, unless a hedge of some kind be planted along the top. Furze seed is often sown for this purpose, and soon forms an excellent fence, which by proper care and clipping will last a long time. But the most common kind of fence for fields is the hedge and ditch, the bank being raised with the earth and sods taken out of the ditch, and the hedge planted on the side of the bank towards the ditch or on the top. Sometimes there is a ditch on both sides. In flat wet lands this last is extremely useful, not only as a fence, but as a drain for the superfluous water. When the ditch is intended to carry off the water, and there is only one, it is of consequence that it should be so placed as to answer this purpose effectually; it should therefore always be on that side of the bank where the ground rises, for otherwise the bank will impede the natural flow of the water, and it will be necessary to cut through it in different places to let the water running from above have an outlet into the ditch. In some extensive inclosures of land great inconvenience has arisen from the neglect of the surveyor in not attending to this circumstance, and setting out the bank on the upper side. Where they are not required as drains, it is a great waste of land to have any ditches, and a simple hedge planted on the surface of the soil is much to be preferred. Of all fences, a live hedge, which is carefully planted, and kept properly cut and trimmed when it is grown up, is by far the best. [Hedge.]

When a fence is required within sight of a dwelling, and it is desirable for it to be concealed, a deep ditch is sometimes dug, and a fence placed in the bottom of it at such a depth as not to appear above the level of the ground. This is called a *sunk fence*. Sometimes a wall is built against a perpendicular side of a ditch, and some very light fence is placed obliquely outwards near the top of it and level with the ground. When it is desired to keep off sheep or cattle from a lawn or pleasure-ground without obstructing the view of the park or the fields, this "ha ha" fence is very useful. A variety of *light fences of iron* have been invented for the same purpose: some of these are fixed and others moveable; some have upright pieces of cast-iron as posts let into oak blocks sunk in the ground, and rods of wrought-iron passing through holes in the uprights; some have wire for the same purpose. But the most common iron fence is composed of separate wrought-iron hurdles which may be moved at pleasure, and are kept together by screwed pins and nuts. They are merely stuck into the ground, for which purpose they have the ends of the uprights sharpened and bent so as to form a foot. By having this bend alternately on the right and on the left, they form a very firm basis when two hurdles are joined, the left foot of the one being strengthened by the right foot of the other. A very neat fence may be made at a small expense by using as posts pieces of young larch-trees four or five inches in diameter, with the bark on, and passing iron rods through holes bored in them at certain distances from each other. A fence of this kind five feet high, with five horizontal rods five-eighths of an inch in diameter, is an excellent protection against cattle, and takes up no ground.

The greatest objection to the ditch and bank fence is that it takes up so much room. If the ditch is three feet wide, the bank will be the same. There is a foot along the ditch, and another along the bank, where the plough cannot reach; there are therefore eight feet lost. If the fields are squares of ten acres each, which is a convenient size, each field will have 1320 feet of fence in length, taking up 10,560 square feet of land, which is nearly a quarter of an acre. If to this be added the outer fences against roads, woods, or commons, it will be found that nearly one acre in twenty-five is taken up by banks and ditches. It is therefore a great saving to have a simple hedge without any ditch, wherever the land is well drained or has a porous subsoil.

It is usual in England to plant trees in the hedge-rows; and it is owing to this practice that England presents such a rich garden-like appearance, wherever there is a hill which enables one to see any extent of country. But trees are a great detriment to the farmer; and where the land is highly manured, the trees draw off much of the rich juices. The prudent tenant considers this in the rent; and although the landlord may now and then sell some timber, he pays dear for it in general by the annual deduction from his income on their account. Stone walls have a dreary appearance to the eye, but they are excellent fences; they take up little ground, they draw nothing out of the soil, they harbour no birds, and they are the best shelter against cold winds in spring. In an agricultural point of view, therefore, walls are to be preferred, unless the soil be favourable to the growth of the whitethorn or the holly; for clipped hedges are kept up at a much smaller expense than walls, and where there is no ditch, hedges take up as little room.

When hedges are preferred, whether with or without a bank and ditch, they must be protected until they are of a certain age; and for this purpose there are particular kinds of fences. When there is a bank and double ditch, and the hedge is planted on the top of the bank, which makes by far the most efficient fence, there are usually two fences, one on each side of the bank. These fences are made of rough posts and rails mortised into the posts. The posts are a foot or 18 inches in the ground, and 2 feet 6 inches out. They are placed in the side of the bank, inclined somewhat outwards, about 4 feet 6 inches asunder. The two rails are let into mortices in the alternate posts, and nailed to the middle post, which is rather slighter. Thus a very formidable fence is made, which those who follow the diversion of hunting, and are not very well mounted, dread to encounter. If there is only a single ditch, it is usual to plant the hedge in the side of the bank a little above the level of the ground. To protect the young thorns from being cropped by the cattle, it is usual to make a dead hedge of stakes with bushes and brambles interwoven on the top of the bank: and if there is pasture land on the side where the ditch is, a post and rail fence is put up along the edge of the ditch till the hedge is grown sufficiently not to be injured by the cattle. When branches of thorns and bushes only are used without stakes, it is called a *foot hedge;* when the branches are interwoven, and the top of the hedge is finished with rods wattled in, it is called a *stake and edder hedge*. Wherever neatness and durability are consulted, the stake and edder hedge is always preferred.

Besides these common fences, there are various others of a light or temporary nature, which are chiefly used in gardens and pleasure-grounds, and also when sheep only are to be kept out, or when a new quick hedge along an orchard or garden has been planted. A cheap and neat fence of this kind is made with stakes only planted in the ground, forming a series of St. Andrew's crosses: or with osier or hazel rods worked between stakes like basket-work, either horizontally and lightly or obliquely and closely. When the rods are split, the appearance is still neater and lighter. A variety of light iron fences made of slender rods or wire have been invented to protect flower-gardens or shrubberies from the depredations of hares and rabbits, and their forms differ according to the fancy and taste of individuals.

FEOD. [Feudal System.]

FEOFFMENT (in law) is that mode of conveyance of lands or real hereditaments in possession where the land passes by force of livery in deed, that is, actual delivery of a portion of the land, as a twig or a turf; or where the parties being on the land the feoffor expressly gives it to the feoffee, &c.; or livery in law or within view, that is, where the parties being within sight of the land, the feoffor refers to it and gives it to the feoffee. A feoffment was the earliest mode of conveying real hereditaments in possession known to the common law. A grant [Deed; Grant] was the mode used when lands subject to an existing estate of freehold, and when rents or other incorporeal hereditaments incapable from their nature of being the subjects of livery, were transferred. The term feoffment is evidently of feudal origin, its latinised form being feoffamentum, from feudare or infeudare, to infeoff, to give a feud. The mode of conveyance is however of much higher antiquity than the feudal system, the mode of transferring property by the delivery of possession being common to all nations in rude ages. (Gilb. 'Ten.' 386.) It prevailed amongst the Anglo-Saxons, who gave possession by the delivery of a twig or a turf, a mode still used in the admission of tenants of copyhold lands. The form of an ancient feoffment was singularly concise. There is a copy of one in the Appendix to the 2nd vol. of Blackstone's 'Commentaries,' No. 1.

Feoffments are now little used. The statute 8 & 9 Vict. c. 106, gave the last blow to a mode of conveyance already nearly obsolete. By this Act corporeal hereditaments are made to lie *in grant* as well as *in livery*. Thus actual or symbolical livery of seisin is unnecessary. See Blackst. 'Comm.' vol. ii. p. 311, Mr. Kerr's Ed.

The essential part of this mode of conveyance is the delivery of possession, or, as it is technically called, livery of seisin. In former times land was frequently conveyed without any deed or writing, by simple delivery. Subsequently it became the custom to have a written instrument called the charter or deed of feoffment [Charter], which declared the intention of the parties to the conveyance. But now, since the Statute of Frauds (29 Car. II. § 3), a written instrument is necessary.

Livery of seisin was at first performed in the presence of the freeholders of the neighbourhood, vassals of the feudal lord; because any dispute relating to the freehold was decided before them as pares curiæ, "equals of the court," of the lord of the fee. But afterwards, upon the decay of the feudal system, the livery was made in the presence of any witnesses; and where a deed was used, the livery was attested by those who were present at it.

Livery in deed may be made by the feoffor or his attorney to the feoffee or his attorney. When lands lie in several counties, as many liveries are necessary; and where lands are out on lease, there must be as many liveries as there are tenants, for no livery can be made but by the consent of the tenant in possession, and the consent of one will not bind the rest. But livery in law or within view can only be given and taken by the parties themselves, though lands in several counties may pass if they all be within view. Livery of this nature requires to be perfected by subsequent entry in the lifetime of the feoffor. Formerly, if the feoffee durst not enter for fear of his life or bodily harm, his claim, made yearly in the form prescribed by law, and called continual claim, would preserve his right. The security of property consequent upon the progress of civilisation having rendered this exception unnecessary, it was abolished by the Statute of Limitations, 3 & 4 Will. IV., c. 27, § 11.

Since the Statute of Uses [Bargain; Sale; Uses] introduced a more convenient mode of conveyance, feoffments have been rarely used in practice, and then rather for their supposed peculiar effects, as wrongful conveyances [Conveyances], than as simple means of transferring property. It has been usual to make corporations convey their own estates by feoffment, in consequence of the supposition that a corporate body cannot stand seised to a use, though it seems that this doctrine only applies to the case of lands being conveyed to a corporation to the use of others. (Gilb. 'On Uses,' Sugd. Ed. 7 note.) Where the object to be attained was the destruction of contingent remainders or the discontinuance of an estate tail, or the acquirement of a fee for the purpose of levying a fine [Fine] or suffering a recovery [Recovery], a feoffment was usually employed. Such indeed was the efficacy attributed to this mode of conveyance by the earlier law writers, that where the feoffor was in possession, however unfounded his title might be, yet his feoffment passed a fee; voidable, it is true, by the rightful owner, but which by the lapse of time might become good even as against him. Being thus supposed to operate as a disseisin to the rightful owner, it was thought till recently that a person entitled to a term of years might by making a feoffment to a stranger pass a fee to him, and then by levying a fine acquire a title by non-claim. This doctrine led to very considerable discussion, and though strictly accordant to the principle of the old law, yet being alike repugnant to the principles of justice and of common sense, it has been overruled.

In the progress of the discussion which ended in overturning the doctrine, arguments against its justice and expediency were used, rather than those founded upon the principles of law, and the bench even resorted to ridicule. Mr. Baron Graham in one case observed, "Yet is this pretended possession of paper and packthread to be called by the tremendous name of disseisin." The recent statute above-mentioned declares that a feoffment shall not have a tortious or wrongful effect, and thus most of the above learning has become mere antiquarianism.

The owner of lands of gavelkind tenure [GAVELKIND] may convey them by feoffment at the age of 15; and therefore in such cases, which are necessarily rare, a feoffment is still resorted to. It was also till lately frequently used for the sake of economy upon small purchases, in order to save the expense of a second deed, which was necessary where the conveyance was by lease and release.

FERMENT. Amongst organic compounds there exist a number of substances, some of animal others of vegetable origin, containing nitrogen, and in which the different constituents are held together by affinities so feeble, as to render them liable to spontaneous changes when exposed to favourable conditions, such as air, moisture, and warmth. Albumen, fibrin, casein, and gluten, for instance, are bodies of this class, which, when removed from vital influence, are exceedingly prone to enter into slow chemical decomposition, the final products of which are usually carbonic acid, water, and ammonia. Such substances during their passage through these chemical changes are termed *ferments*, and are capable of inducing, by mere contact with other bodies of more stable character, certain chemical changes. This operation of inducing chemical change by contact with a ferment is denominated *fermentation*, and is frequently employed both in chemistry and the arts for producing various interesting transformations. It is thus that alcohol is produced from sugar by the ferment yeast; the peculiar oil to which mustard owes its origin is generated by a similar reaction; and recently Berthellot has succeeded in transforming glycerin into grape-sugar by mere contact with a small fragment of animal membrane. As a ferment is essentially a body in a state of chemical change, it follows that the exact composition of such bodies is difficult, if not impossible, to determine, and hence we are unacquainted with the formula of any ferment. The following are the best known ferments:—

1. *Yeast*, produced when a saccharine solution, containing nitrogenous matter, as white of egg, is exposed to the air at a temperature of about 80° Fahr. The yeast separates as a kind of scum or froth. It transforms sugar into alcohol and carbonic acid, malic acid into succinic, acetic, and carbonic acids, and tannic acid into gallic acid.

2. *Diastase.* This ferment exists in malted barley, and possesses the property of converting starch into dextrin and grape-sugar.

3. *Synaptase* or *Emulsin*, exists in almonds, and converts amygdalin into oil of bitter almonds (*hydride of benzoyl*), formic acid, hydrocyanic acid, and sugar. [AMYGDALIN.] It also converts salicin into sugar and saligenin. According to Thompson and Richardson, when synaptase is boiled with caustic baryta, it yields *emulsic acid*.

4. *Myrosin*, contained in mustard. In contact with water and myronic acid, which is also contained in mustard, it produces oil of mustard.

5. *Decaying cheese*, in contact with cane- or milk-sugar, transforms them first into lactic acid, and then, by further contact, converts this lactic acid into butyric acid, carbonic acid, and hydrogen. The latter transformation is sometimes termed the *butyric fermentation*.

It must be remarked that all these fermentive processes require the presence of water and moderate warmth. They are frequently, but not invariably, attended with the evolution of gases. In many fermentive processes, the ferment itself suffers very little change, although large quantities of the fermentescible substance may have undergone transformation. The ferment does not, therefore, combine with any of the products of transformation; it appears only to communicate, by contact with the fermentescible substance, an impulse to the molecules of the latter, which determines their splitting up into two or more new compounds.

Processes which are generally regarded as analogous to the above, but which are less understood, can be induced in the bodies of living animals; thus when morbific matter, the fluid of putrefying flesh, vaccine matter, &c., are brought into contact with circulating blood, the latter suffers remarkable changes, attended with the production of certain forms of disease; and it is also more than probable that gaseous ferments are amongst the conditions necessary for the production of most, if not all, infectious diseases, such as typhus, cholera, scarlatina, &c.

FERMENTATION. [FERMENT.]

FERRIC ACID. [IRON.]

FERRICYANIDES. *Ferridcyanides.* Salts of FERRIDCYANIC ACID.

FERRIDCYANIC ACID ($H_3C_{12}N_6Fe_2$), *Hydroferridcyanic acid.* An acid analogous to FERROCYANIC ACID, obtained in red crystals by suspending ferridcyanide of lead in water, and passing sulphuretted hydrogen through the mixture. [CYANOGEN.]

FERROCYANIC ACID (H_2FeCy_3), *Hydro-ferrocyanic Acid.* Discovered by Porret, and by him called *ferruretted chyazic acid.* He procured it from the decomposition of ferrocyanide of potassium by the action of tartaric acid, or from ferrocyanide of barium by means of sulphuric acid. According to Berzelius it is best prepared by diffusing recently precipitated ferrocyanide of copper or lead through water, and passing hydrosulphuric acid gas through the mixture; the sulphur precipitates the copper or lead in the state of sulphuret, while the hydrogen, uniting with the cyanogen and iron, forms ferrocyanic acid. Any excess of sulphuric acid is to be got rid of by adding ferrocyanide of the metal employed. The solution should be quickly filtered and evaporated in vacuo over sulphuric acid. A white residue is obtained which when dissolved in water is inodorous, sour, reddens litmus paper, decomposes the alkaline carbonates with effervescence, forms ferrocyanides with them, and exhibits other proofs of a strong acid. When exposed to spontaneous evaporation in a warm place, colourless radiating crystals are observed, which have the appearance of four-sided prisms. This acid is decomposed by long exposure to the air, Prussian blue being formed and precipitated; this is also produced by adding to it a persalt of iron.

The aqueous solution is also decomposed by boiling; and when submitted to destructive distillation it yields hydrocyanic acid, hydrocyanate, and carbonate of ammonia, and carburet of iron remains. [CYANOGEN.]

FERROCYANIDES. Salts of FERROCYANIC ACID.

FERRY, an exclusive privilege for the carriage of horses and men across a river or arm of the sea for reasonable toll. The owner of a ferry cannot suppress it and put up a bridge in its stead without a licence; but he is bound to keep it always in repair and readiness, with expert men, and reasonable toll, for neglect of which he is liable to be punished by indictment. And, therefore, if a ferry is erected so near to an ancient ferry as to draw away its custom, it is a nuisance to the owner of the old one, for which the law will give him remedy by action. The ferry is in respect of the landing-place, and not of the water; and in every ferry the land on both sides ought originally to have been in the same person, otherwise he could not have granted the ferry. As all existing ferries are of great antiquity, and generally connect roads abutting on either side of the water, the original unity of possession is now mere matter of curiosity. A ferry is considered for some purposes a common highway.

FESCENNINE VERSES were rude licentious verses sung by young men at weddings, and before the door of the nuptial chamber. This was a very ancient custom at Rome: the practice, and some of the verses themselves, are said to have been introduced from Fescennium, an old Etruscan town near the present site of Civita Castellana. Festus and others derive the name Fescennine from *fascinum*, a charm or evil influence, which was supposed to have the power of depriving persons of their physical strength, and which the Fescennine verses were intended to avert. Valetta, a Neapolitan lawyer and poet of the 18th century, has written a curious book on the "Fascino," or evil eye, the belief of which is still prevalent at Naples. The Fescennine verses were distinct from the epithalamia, which were more refined and regular compositions. [EPITHALAMIUM.] Horace (Epist. ii. 1) says that Fescennine verses were sung by the country-people at harvest-time; and the custom of dealing out licentious jokes upon each other and upon strangers passing by is still retained by the vintagers in various parts of Italy. The name of Fescennine was given in general to licentious and satirical epigrams. Octavianus is said to have written some of this character against Pollio, in the time of the Triumvirate.

FEUD. [FEUDAL SYSTEM.]

FEUDAL SYSTEM. In treating of this subject, we shall endeavour to present a concise and clear view of the principles of what is called the feudal system, to indicate the great stages of its history, especially in our own country, and to state briefly the leading considerations to be taken into account in forming an estimate of its influence on the civilisation of modern Europe.

The essential constituent and distinguishing characteristic of the species of estate called a feud or fief was from the first, and always continued to be, that it was not an estate of absolute and independent ownership. The ultimate property, or *dominium directum*, as it was called, remained in the grantor of the estate. The person to whom it was granted did not become its owner, but only its tenant or holder: he possessed the *dominium utile* only. There is no direct proof that fiefs were originally resumable at pleasure; but the position is laid down in almost every writer on the feudal system, and, if not to be made out by any decisive instances, it is at least strongly supported not only by general considerations of probability, but also by some indicative facts. The fief was certainly at one time revocable, at least on the death of the grantee. In receiving it, therefore, the grantee had received not an absolute gift, but only a loan, or at most an estate for his own life.

This being established as the true character of a primitive feud or fief, may perhaps throw some light upon the much disputed etymology and true meaning of the word. *Feudum* has been derived by some from a Latin, by others from a Teutonic root. The principal Latin origins proposed are *fœdus* (a treaty) and *fides* (faith). The supposition of the transformation of either of these into feudum seems unsupported by any proof. These derivations, in fact, are hardly better than another resolution of the puzzle that has been gravely offered,—namely, that feudum is a word made up of the initial letters of the words "fidelis ero ubique domino vero meo." The chief Teutonic etymologies proposed have been from the old German *faida*, the Danish *feide*, or the modern German *vehd*, all meaning battle-feud or dissension; but the most acceptable is from *fe* or *fee*, which it is said signifies wages or pay for service, the word *od* or *odh*, to which the signification of possession or property is assigned, being combined with it. Sir Francis Palgrave ('Rise and Progress of Engl. Com.,' pp. 204–207) doubts if the word *feudum* ever existed. The true word seems to be *ferdum*, or *feftum*. *Fiev* or *fief* (latinised into *ferodium*, which some contracted into *ferdum*, and others, by omitting the *v*, into *feudum*) he conceives to be *fitef*, or *phitef*, and that again to be a colloquial abbreviation of *emphyteusis*, pronounced *emphytefsis*, a well-known term of the Roman law for an estate granted to be held not absolutely, but with the ownership still in the grantor and the usufruct only in the hands of the grantee. It is certain that *emphyteusis* was used in the middle ages as synonymous with *precaria;* that *precariæ*, and also *præstitæ*, or *præstariæ* (literally loans), were the same with *beneficia ;* and that *beneficia* under the emperors were the same or near the same as *fiefs*. The word *feu*, which in Scotland means an estate held of a superior or lord, for which, as explained by Erskine ('Principles,' b. ii., tit. 4), a rent, or feu-duty, as it is called, is always paid, has "a strong resemblance to the Roman *emphyteusis*, in the nature of the right, the yearly duty payable by the vassal, the penalty in the case of not punctual payment, and the restraint frequently laid upon vassals not to alien without the superior's consent."

The origin of the system of feuds has been a fertile subject of speculation and dispute. If we merely seek for the existence of a kind of landed tenure resembling that of the fief in its essential principle, it is probable that such may be discovered in various ages and parts of the world. But feuds alone are not the feudal system; they are only one of the elements out of which that system grew. In its entireness, it is certain that the feudal system never subsisted anywhere before it arose in the middle ages in those parts of Europe in which the Germanic nations settled themselves after the subversion of the Roman empire.

Supposing feud to be the same word with the Roman emphyteusis, it does not follow that the Germanic nations borrowed the notion of this species of tenure from the Romans. It is perhaps more probable that it was the common form of tenure among them before their settlement in the Roman provinces. It is to be observed that the emphyteusis, the precaria, the beneficium, only subsisted under the Roman scheme of polity in particular instances, but they present themselves as the very genius of the Germanic scheme. What was only occasional under the one became general under the other. In other words, if the Romans had feuds, it was their Germanic conquerors who first established a system of feuds; upon their first settlement in the conquered provinces.

We know so little with certainty respecting the original institutions of the Germanic nations, that it is impossible to say how much they may have brought with them from their northern forests, or how much they may have borrowed from the imperial polity, of the other chief element which enters into the system of feudalism, the connection subsisting between the grantor and the grantee of the fief, the person having the property and the person having the usufruct, or, as they were respectively designated, the suzerain or lord, and the tenant or vassal. Tenant may be considered as the name given to the latter in reference to the particular nature of his right over the land as the *holder* of it, in short; vassal, that denoting the particular nature of his personal connection with his lord. The former has been already explained; the consideration of the latter introduces a new view. By some writers the feudal vassals have been derived from the *comites*, or officers of the Roman imperial household [COUNT]; by others from the *comites*, or companions, mentioned by Tacitus ('German.' 13, &c.) as attending upon each of the German chiefs in war. The latter opinion is ingeniously maintained by Montesquieu (xxx. 3). One fact appears to be certain, and is of some importance, namely, that the original vassali or vassi were merely noblemen who attached themselves to the court and to attendance upon the prince, without necessarily holding any landed estate or beneficium by royal grant. In this sense the words occur in the early part of the 9th century. Vassal has been derived from the Celtic *gwas*, and from the German *gesell*, which are probably the same word, and of both of which the original signification seems to be a helper, or subordinate associate, in labour of kind.

If the vassal was at first merely the associate of or attendant upon his lord, nothing could be more natural than that, when the latter came to have land to give away, he should most frequently bestow it upon his vassals, both as a reward for their past and a bond by which he might secure their future services. If the peculiar form of tenure constituting the fief did not exist before, here was the very case which would suggest it. At all events, nothing could be more perfectly adapted to the circumstances. The vassal was entitled to a recompense; at the same time it was not the interest of the prince to sever their connexion, and to allow him to become independent; probably that was as little the desire of the vassal himself; he was conveniently and appropriately rewarded therefore by a fief, that is, by a loan of land, the profits of which were left to him as entirely as if he had obtained the ownership of the land, but his precarious and revocable tenure of which, at the same time, kept him bound to his lord in the same dependence as before.

Here then we have the union of the feud and vassalage—two things which remained intimately and inseparably combined so long as the feudal system existed. They may have originally been quite distinct, and merely been thrown into combination by circumstances. It is possible that there were vassals who were not feudatories, or feudatories who were not vassals. But when the advantage of the association of the two characters came to be perceived, it would be established as essential to the completeness of each. Every vassal would have a fief, and every person to whom a fief was granted would be a vassal, and thus a vassal and the holder of a fief come to signify one and the same thing.

Fiefs are supposed to have been at first entirely precarious, that is to say, resumable at any time at the pleasure of the grantor. But if this state of things ever existed, it probably did not last long. Even from the first it is most probable that many fiefs were granted for a certain term of years or for life. And in those of all kinds a substitute for the original precariousness of the tenure was soon found, which while it equally secured the rights and interests of the lord, was much more honourable and in every way more advantageous for the vassal. This was the method of attaching him by certain oaths and solemn forms, which, besides their force in a religious point of view, were so contrived as to appeal also to men's moral feelings, and which therefore it was accounted not only impious but infamous to violate. The relation binding the vassal to his lord was made to wear all the appearance of a mutual interchange of benefits,—of bounty and protection on the one hand, of gratitude and service due on the other; and so strongly did this view of the matter take possession of men's minds, that in the feudal ages even the ties of natural relationship were looked upon as of inferior obligation to the artificial bond of vassalage.

As soon as the position of the vassal had thus been made stable and secure, various changes would gradually introduce themselves. The vassal would begin to have his fixed rights as well as his lord, the oath which he had taken measuring and determining both these rights and his duties. The relation between the two parties would cease to be one wholly of power and dominion on the one hand, and of mere obligation and dependence on the other. If the vassal performed that which he had sworn, nothing more would be required of him. Any attempt of his lord to force him to do more would be considered an injustice. Their connection would now assume the appearance of a mutual compact, imposing corresponding obligations upon both, and making protection as much a duty in the lord as gratitude and service in the vassal.

Other important changes would follow this fundamental change, or would take place while it was advancing to completion. After the fief had come to be generally held for life, the next step would be for the eldest son usually to succeed his father. His right so to succeed would next be established by usage. At a later stage fiefs would become, as they did, descendible in the collateral as well as in the direct line. At a still later, they became inheritable by females as well as by males. There is much difference of opinion, however, as to the dates at which these several changes took place. Some writers conceive that fiefs first became hereditary in France under Charlemagne; others, however, with whom Mr. Hallam agrees, maintain that there were hereditary fiefs under the first race of French kings. It is supposed not to have been till the time of the first Capets in the end of the 10th century that the right of the son to succeed the father was established by law in France. Conrad II., surnamed the Salic, who became emperor in 1024, is generally believed to have first established the hereditary character of fiefs in Germany.

Throughout the whole of this progressive development of the system, however, the original nature of the fief was never forgotten. The ultimate property was still held to be in the lord; and that fact was very distinctly signified, not only by the expressive language of forms and symbols, but by certain liabilities of the tenure that gave still sharper intimation of its true character. Even after fiefs became descendible to heirs in the most comprehensive sense, and by the most fixed rule, every new occupant of the estate had still to make solemn acknowledgement of his vassalage, and thus to obtain, as it were, a renewal of the grant from the lord. He became bound to discharge all services and other dues as fully as the first grantee had been. Above all, in certain circumstances, as, for example, if the tenant committed treason or felony, or if he left no heir, the estate would still return by forfeiture or escheat to the lord, as to its original owner.

Originally fiefs were granted only by sovereign princes; but after estates of this description, by acquiring the hereditary quality, came to be considered as property to all practical intents and purposes, their holders proceeded, on the strength of this completeness of possession, themselves to assume the character and to exercise the rights of lords, by the practice of what was called subinfeudation, that is, the alienation of portions of their fiefs to other parties, who thereupon were placed in the same or a similar relation to them as that in which they stood to the prince. The vassal of the prince became the lord over other vassals; in this latter capacity he was called a mesne (that is, an intermediate) lord; he was a lord and a vassal at the same time. In the same manner the vassal of a mesne lord might become also the lord of other arrere vassals, as those vassals that held of a mesne lord were designated. This process sometimes produced curious results; for a lord might in this way actually become the vassal of his own vassal, and a vassal lord over his own lord.

From whatever cause it may have happened (which is matter of dispute), in all the continental provinces of the Roman empire which were conquered and occupied by the Germanic nations, many lands were from the first held, not as fiefs, that is, with the ownership in one party and the usufruct in another, but as allodia, that is, in full and entire ownership. [ALLODIUM.] The holder of such an estate, having no lord, was of course free from all the exactions and burdens which were incidental to the vassalage of the holder of a fief. He was also, however, without the powerful protection which the latter enjoyed; and so important was this protection in the turbulent state of society which existed in Europe for some ages after the dissolution of the empire of Charlemagne, that in fact most of the allodialists in course of time exchanged their originally independent condition for the security and subjection of that of the feudatory. "During the 10th and 11th centuries," says Mr. Hallam, "it appears that allodial lands in France had chiefly become feudal; that is, they had been surrendered by their proprietors, and received back again upon the feudal conditions; or, more frequently perhaps, the owner had been compelled to acknowledge himself the man or vassal of a suzerain, and thus to confess an original grant which had never existed. Changes of the same nature, though not perhaps so extensive or so distinctly to be traced, took place in Italy and Germany. Yet it would be inaccurate to assert that the prevalence of the feudal system has been unlimited; in a great part of France allodial tenures always subsisted, and many estates in the empire were of the same description."

After the conquest of England by the Normans, the *dominium directum*, or property of all the land in the kingdom, was considered as vested in the crown. "All the lands and tenements in England in the hands of subjects," says Coke, "are holden mediately or immediately of the king; for in the law of England we have not properly allodium." This universality of its application therefore may be regarded as the first respect in which the system of feudalism established in England differed from that established in France and other continental countries. There were also various other differences. The Conqueror, for instance, introduced here the practice unknown on the continent of compelling the arrere vassals, as well as the immediate tenants of the crown, to take the oath of fealty to himself. In other countries a vassal only swore fealty to his immediate lord; in England, if he held of a mesne lord, he took two oaths, one to his lord and another to his lord's lord. It may be observed, however, that in those times in which the feudal principle was in its greatest vigour the fealty of a vassal to his immediate lord was usually considered as the higher obligation; when that and his fealty to the crown came into collision, the former was the oath to which he adhered. Some feudists indeed held that his allegiance to the crown was always to be understood as reserved in the fealty which a vassal swore to his lord; and the Emperor Frederick Barbarossa decreed that in every oath of fealty taken to an inferior lord there should be an express reservation of the vassal's duty to the emperor. But the double oath exacted by the Norman conqueror did not go so far as this. It only gave him at the most a concurrent power with the mesne lord over the vassals of the latter, who in France were nearly removed altogether from the control of the royal authority. A more important difference between the English and French feudalism consisted in the greater extension given by the former to the rights of lords generally over their vassals by what were called the incidents of wardship and marriage. The wardship or guardianship of the tenant during minority, which implied both the custody of his person and the appropriation of the profits of the estate, appears to have been enjoyed by the lord in some parts of Germany, but no where else except in England and Normandy. The right of marriage (maritagium) originally implied only the power possessed by the lord of tendering a husband to his female ward while under age: if she rejected the match, she forfeited the value of the marriage; that is, as much as any one would give to the lord for permission to marry her. But the right was afterwards extended so as to include male as well as female heirs; and it also appears that although the practice might not be sanctioned by the law, some of the Anglo-Norman kings were accustomed to exact penalties from their female vassals of all ages, and even from widows, for either marrying without their consent, or refusing such marriages as they proposed. The seignorial prerogative of marriage, like that of wardship, was peculiar to England and Normandy, and to some parts of Germany.

It has been very usual to represent military service as the essential peculiarity of a feudal tenure. But the constituent and distinguishing element of that form of tenure was its being a tenancy merely, and not an ownership; the enjoyment of land for certain services to be performed. In the state of society however in which the feudal system grew up, it was impossible that military service should not become the chief duty to which the vassal was bound. It was in such a state of society the most important service which he could render to his lord. It was the species of service which the persons to whom fiefs were first granted seem to have been previously accustomed to render, and the continuance of which accordingly the grant of the fief was chiefly intended to secure. Yet military service, or knight service, as it was called in this country, though the usual, was by no means the necessary or uniform condition on which fiefs were granted. Any other honourable condition might be imposed which distinctly recognised the *dominium directum* of the lord. [KNIGHT-SERVICE.]

Another common characteristic of fiefs, which in like manner arose incidentally out of the circumstances of the times in which they originated, was that they usually consisted of land. Land was in those times nearly the only species of wealth that existed; certainly the only form of wealth that had any considerable security or permanency. Yet there are not wanting instances of other things, such as pensions and offices, being granted as fiefs. It was a great question nevertheless among the feudists whether a fief could consist of money, or of any thing else than land; and the most eminent authorities have maintained that it could not. The preference thus shown for land by the spirit of the feudal customs has perhaps left deeper traces both upon the law, the political constitution, and the social habits and feelings of our own and other feudal countries than any other part of the system. We have thence derived not only the marked distinction by which our law still discriminates certain amounts of interest in lands and tenements under the name of *real* property from property of every other kind, but also the ascendency retained by the former in nearly every respect in which such ascendency can be upheld either by institutions or by opinion.

The grant of land as a fief, especially when it was a grant from the suzerain, or supreme lord, whether called king or duke, or any other name, was, sometimes at least, accompanied with an express grant of jurisdiction. Thus every great tenant exercised a jurisdiction civil and criminal over his immediate tenants: he held courts and administered the laws within his lordship like a sovereign prince. It appears that the same jurisdiction was often granted by the crown to the abbeys with their lands. The formation of MANORS in this country appears to have been consequent upon the establishment of feudalism. The existence of manor-courts, and so many small jurisdictions within the kingdom, is one of the most permanent features of that polity which the Normans stamped upon this country.

In the infancy of the feudal system it is probable that the vassal was considered bound to attend his lord in war for any length of time during which his services might be required. Afterwards, when the situation of the vassal became more independent, the amount of this kind of service was fixed either by law or by usage. In England the whole country was divided into about 60,000 knights' fees; and the tenant of each of these appears to have been obliged to keep the field at his own expense for forty days on every occasion on which his lord chose to call upon him. For smaller quantities of land proportionately shorter terms of service were due: at least such is the common statement; although it seems improbable that the individuals composing a feudal army could thus have the privilege of returning home some at one time, some at another. Women were obliged to send their substitutes; and so were the clergy, certain persons holding public offices, and men past the age of sixty, all of whom were exempted from personal service. The rule or custom however both as to the duration of the service, and its extent in other respects, varied greatly in different ages and countries.

The other duties of the vassal were rather expressive of the relation of honourable subordination in which he stood to his lord than services of any real or calculable value. They are thus summed up by Mr. Hallam:—"It was a breach of faith to divulge the lord's counsel, to conceal from him the machinations of others, to injure his person or fortune, or to violate the sanctity of his roof and the honour of his family. In battle he was bound to lend his horse to his lord when dismounted; to adhere to his side while fighting, and to go into captivity as a hostage for him when taken. His attendance was due to the lord's courts, sometimes to witness and sometimes to bear a part in the administration of justice."

There were however various other substantial advantages derived by the lord. We have already mentioned the rights of wardship and of marriage, which were nearly peculiar to the dominions of the English crown. Besides these, there were the payment, called a relief, made by every new entrant upon the possession of the fief, the escheat of the land to the lord when the tenant left no heir, and its forfeiture to him when the tenant was found guilty either of a breach of his oath of fealty, or of felony. There was besides a fine payable to the lord upon the alienation by the tenant of any part of the estate, if that was at all permitted. Finally, there were the various aids, as they were called, payable by the tenant. "These," observes Mr. Hallam, "depended a great deal upon local custom, and were often extorted unreasonably. Du Cange mentions several as having existed in France; such as an aid for the lord's expedition to the Holy Land, for marrying his sister or eldest son, and for paying a relief to his suzerain on taking possession of his land. Of these the last appears to have been the most usual in England. But this and other aids occasionally exacted by the lords were felt as a severe grievance; and by Magna Charta three only are retained—to make the lord's eldest son a knight, to marry his eldest daughter, and to redeem his person from prison. They were restricted to nearly the same description by a law of William I. of Sicily, and by the customs of France. These feudal aids are deserving of our attention as the beginnings of taxation, of which for a long time they in a great measure answered the purpose, till the craving necessities and covetous policy of kings substituted for them more durable and onerous burthens."

The principal ceremonies used in conferring a fief were homage, fealty, and investiture. The two first of these cannot be more distinctly or more shortly described than in the words of Littleton: "Homage is the most honourable service, and most humble service of reverence, that a frank tenant may do to his lord: for when the tenant shall make homage to his lord, he shall be ungirt and his head uncovered, and his lord shall sit and the tenant shall kneel before him on both his knees, and hold his hand jointly together between the hands of his lord, and shall say thus: I become your man, from this day forward, of life and limb, and of earthly worship, and unto you shall be true and faithful, and bear you faith for the tenements that I claim to hold of you, saving the faith that I owe to our sovereign lord the king; and then the lord, so sitting, shall kiss him." Religious persons and women instead of "I become your man," said, "I do homage unto you." Here it is to be observed there was no oath taken; the doing of fealty consisted wholly in taking an oath, without any obeisance. "When a freeholder (frank tenant)," says Littleton, "doth fealty to his lord, he shall hold his right hand upon a book, and shall say thus: Know ye this, my lord, that I shall be faithful and true unto you, and faith to you shall bear for the lands which I claim to hold of you, and that I shall lawfully do to you the customs and services which I ought to do at the terms assigned, so help me God and his saints; and he shall kiss the book. But he shall not kneel when he maketh his fealty, nor shall make such (that is, any such, *tiel*,) humble reverence as is aforesaid in homage." "Investiture or the actual conveyance of feudal lands," says Mr. Hallam, "was of two kinds; proper and improper. The first was an actual putting in possession upon the ground, either by the lord or his deputy; which is now called in our law livery of seisin. The second was symbolical, and consisted in the delivery of a turf, a stone, a wand, a branch, or whatever else might have been made usual by the caprice of local custom. Du Cange enumerates not less than 98 varieties of investitures." The mode of conveying lands in England by feoffment is derived from the feudal investiture. [Feoffment.] The practice of giving infeftment in Scotland, is neither more nor less than symbolical investiture.

The feudal system may be regarded as having nearly reached its maturity and full development at the time of the Norman conquest. It appears accordingly to have been established here immediately or very soon after that event in as pure, strict, and comprehensive a form as it ever attained in any other country. The whole land of the kingdom, as we have already mentioned, was without any exception either in the hands of the crown, or held in fief by the vassals of the crown, or of them by sub-infeudation. Those lands which the king kept were called his demesne (the Terræ Regis of the Domesday Survey), and thus the crown had a number of immediate tenants, like any other lord, in the various lands reserved in nearly every part of the kingdom. No where else, also, before the restrictions established by the charters, were the rights of the lord over the vassal stretched in practice nearer to their extreme theoretical limits. On the other hand, the vassal had arrived at what we may call his ultimate position in the natural progress of the system; the hereditary quality of feuds was fully established; his ancient absolute dependence and subjection had passed away; under whatever disadvantages his inferiority of station might place him, he met his lord on the common ground of their mutual rights and obligations; there might be considerable contention about what these rights and obligations on either side were, but it was admitted that on both sides they had the same character of real, legally binding obligations, and legally maintainable rights.

This settlement of the system however was anything rather than an assurance of its stability and permanency. It was now held together by a principle altogether of a different kind from that which had originally created and cemented it. That which had been in the beginning the very life of the relation between the lord and the vassal had now in great part perished. The feeling of gratitude could no more survive than the feeling of dependence on the part of the latter after feuds became hereditary. A species of superstition, indeed, and a sense of honour, which in some degree supplied the place of what was lost, were preserved by oaths and ceremonies, and the influence of habit and old opinion; but these were at the best only extraneous props; the self-sustaining strength of the edifice was gone. Thus it was the tendency of feudalism to decay and fall to pieces under the necessary development of its own principle.

Other causes called into action by the progress of events conspired to bring about the same result. The very military spirit which was fostered by the feudal institutions, and the wars, defensive and aggressive, which they were intended to supply the means of carrying on, led in course of time to the release of the vassal from the chief and most distinguishing of his original obligations, and thereby, it may be said, to the rupture of the strongest bond that had attached him to his lord. The feudal military army was at length found so inconvenient a force that soon after the accession of Henry II. the personal service of vassals was dispensed with, and a pecuniary payment, under the name of escuage, accepted in its stead. From this time the vassal was no longer really the defender of his lord; he was no longer what he professed to be in his homage and his oath of fealty; and one effect of the change must have been still farther to wear down what remained of the old impressiveness of these solemnities, and to reduce them nearer to mere dead forms. The acquisition by the crown of an army of subservient mercenaries, in exchange for its former inefficient and withal turbulent and unmanageable army of vassals, was in fact the discovery of a substitute for the main purpose of the feudal polity. Whatever nourished a new power in the commonwealth, also, took sustenance and strength from this ancient power. Such must in an especial degree have been the effect of the growth of towns, and of the new species of wealth, and, it may be added, the new manners and modes of thinking, created by trade and commerce.

The progress of sub-infeudation has sometimes been represented as having upon the whole tended to weaken and loosen the fabric of feudalism. It "demolished," observes Blackstone (ii. 4), "the ancient simplicity of feuds; and an inroad being once made upon their constitution, it subjected them in a course of time to great varieties and innovations. Feuds began to be bought and sold, and deviations were made from the old fundamental rules of tenure and succession, which were held no longer sacred when the feuds themselves no longer continued to be purely military." But the practice of sub-infeudation would rather seem to have been calculated to carry out the feudal principle, and to place the whole system on a broader and firmer basis, and this has been found to be the effect in Scotland. It would be more correct to ascribe the demolition of the fabric of feudalism, to which we have now nearly arrived, to the prohibition against sub-infeudation. The effect of this practice was to deprive the lord of his forfeitures and escheats and the other advantages of his seigniory, and various attempts therefore were made to check or altogether prevent it, in which the crown and the tenants in chief, whose interests were most affected, seem to have joined. One of the clauses of the great charter of Henry III. (the thirty-second) appears to be intended to restrict sub-infeudation (although the meaning is not quite clear), and it is expressly forbidden by the statute of *Quia Emptores* (18 Edw. I., c. 1). This however was originally the only way in which the holder of a fief could alienate any part of his estate without the consent of his lord; and it therefore became necessary to provide some other mode of effecting that object, for it seems to have been felt that after alienation had been allowed so long to go on under the guise of sub-infeudation, to restrain it altogether would be no longer possible. The consequence was, that, as a compensation for the prohibition of sub-infeudation, the old prohibition against alienation was removed; lands were allowed to be alienated, but the purchaser or grantee did not hold them of the vendor or grantor, but held them exactly as the grantor did; and such is still the legal effect in England when a man parts with his entire interest in his lands. This change was effected by the statute of *Quia Emptores* with regard to all persons except the immediate tenants of the crown, who were permitted to alienate on paying a fine to the king by the statute 1 Edw. III. c. 12. Thus at the same time that a practice strictly accordant to the spirit of feudalism, and eminently favourable to its conservation and extension, was stopped, another practice, altogether adverse to its fundamental principles, was introduced and established, that of allowing *voluntary* alienation by persons during their lifetime.

It was a consequence of feudal principles, that a man's lands could not be subjected to the claims of his creditors. This restraint upon what may be called *involuntary* alienation has been removed by the successive enactments which have had for their object to make a man's lands liable for his debts: although, it is only after a lapse of nearly six hundred years since the statute of Acton Burnell, that the lands of a debtor have been subjected to the just demands of his creditors. This statute of Acton Burnell, passed 11 Ed. I. (1283), made the devisable burgages, or burgh tenements, of a debtor saleable in discharge of his debts. By the Statute of Merchants (13 Ed. I., st. 13), a debtor's lands might be delivered to his merchant creditor till his debt was wholly paid out of the profits. By the 18th chapter of the Statute of Westminster the Second, passed the same year, a moiety of a debtor's land was subjected to execution for debts recovered by judgment [Elegit]; and finally, by several modern statutes, the whole of a bankrupt debtor's lands have become absolutely saleable for the payment of his debts. Further, by 3 & 4 Will. IV. c. 104, all a deceased person's estate in lands, of whatever kind, is liable to the payment of his debts, both those on specialty and those on simple contract.

An attempt had early been made to restore in part the old restraints upon *voluntary* alienation by the statute 13 Ed. I. c. 1, entitled 'De Donis Conditionalibus,' which had for its object to enable any owner of an estate, by his own disposition, to secure its descent in perpetuity in a particular line. So far as the statute went, it was an effort to strengthen the declining power of feudalism. The effect was to create what were called estates tail, and to free the tenant in tail from many liabilities of his ancestor to which he would be subject if he were seised of the same lands in fee-simple. [Estate.] The power which was thus conferred upon landholders of preventing the alienation of their lands remained in full force for nearly two centuries, till at last, in the reign of Edward IV., by the decision of the courts (A.D. 1472) the practice of barring estates tail by a common recovery was completely established. [Recovery, Common.]

The practice of conveying estates by fine, which was of great antiquity in England, and the origin of which is referred to the time of Stephen or Henry II., was regulated by various statutes (among others, by 4 Henry VII.) and contributed materially to facilitate the transfer of lands in general, but more particularly to bar estates tail.

[Fine.] By 32 Henry VIII. c. 28, tenants in tail were enabled to make leases for three lives or twenty-one years, which should bind their issue. The 26 Henry VIII. c. 13, also, had declared all estates of inheritance, in use or possession, to be forfeited to the king upon any conviction of high treason, and thus destroyed one of the strongest inducements to the tying up of estates in tail, which hitherto had only been forfeitable for treason during the life of the tenant in tail.

Another mode by which the feudal restraints upon *voluntary* alienation came at length to be extensively evaded was the practice introduced, probably about the end of the reign of Edward III., of granting lands to persons to *uses*, as it was termed; that is, the new owner of the land received it not for his own use, but on the understanding and confidence that he would hold the land for such persons and for such purposes as the grantor then named or might at any time afterwards name. Thus an estate in land came to have two qualities or natures, so to speak, one of which was the legal ownership, and the other the right to the profits or the *use;* and this use could be transferred by a man's last *will* at a time when, the land itself being still bound in the fetters of feudal restraint, could not be transferred by will, except where it was devisable, as in Kent and some other parts of England, by special custom. The person who thus obtained the use or profits of the estate—the *cestui que use*, as he is called in law—was finally converted into the actual owner of the land to the same amount of interest as he had in the use (A.D. 1535) by the Statute of Uses (27 Hen. VIII. c. 10), and thus the power of devising land which had been enjoyed by the mode of uses was taken away. But this important element in the feudal system, the restraint on the disposition of lands by will, could no longer be maintained consistently with the habits and opinions then established, and accordingly, by stat. 32 Hen. VIII. (explained by 34 Hen. VIII.), all persons were allowed to dispose of their freehold lands held in fee-simple by a will in writing, subject to certain restrictions as to lands held by knight service either of the king or any other, which restrictions were removed by the stat. 12 Chas. II. c. 24, which abolished military tenures. [Uses.]

Notwithstanding these successive assaults upon certain parts of the ancient feudalism, the main body of the edifice still remained almost entire. It is said that the subject of the abolition of military tenures was brought before the parliament in the 18th of James I., on the king's recommendation; but at that time nothing was done in the matter. When the civil war broke out in 1641, the profits of marriage, wardship, and of most of the other old feudal prerogatives of the crown, were for some time still collected by the parliament, as they had formerly been by the king. The fabric of the feudal system in England, however, was eventually shattered by the storm of the great rebellion. The Court of Wards was in effect discontinued from 1645. The restoration of the king could not restore what had thus been in practice swept away. By the above-mentioned statute (12 Car. II. c. 24) it was accordingly enacted, that from the year 1645 the Court of Wards and Liveries, and all wardships, liveries, primer-seisins, values, and forfeitures of marriage, &c., by reason of any tenure of the king's majesty, or of any other by knights' tenures, were taken away and discharged, together with all fines for alienations, tenure by homage, escuage, aids pur file marrier and pur fair fitz chevalier, &c.; and that all tenures of any honours, manors, lands, tenements or hereditaments, or any estate of inheritance at the common law, held either of the king or of any other person or persons, bodies politic or corporate, were turned into free and common soccage, to all intents and purposes. [Soccage.] By the same statute, every father was empowered by deed or will, executed in the presence of two witnesses, to appoint persons to have the guardianship of his infant and unmarried children, and to have the custody and management of their property. It was not till after the lapse of nearly another century that similar incidents of feudalism were put an end to in Scotland by two statutes, passed after the Rebellion,—the 20 Geo. II. c. 43, entitled 'An Act for abolishing Heritable Jurisdictions;' and the 20 Geo. II. c. 50, entitled 'An Act for taking away the Tenure of Wardholding in Scotland.' It is only within the last few years that estates-tail in Scotland have been relieved from the strictest fetters of a destination in perpetuity.

We have enumerated the principal statutes which may be considered as having broken in upon the integrity of the feudal system, considered in reference to the power which the *tenant* of land can now exercise over it, and the right which others can enforce against him in respect of his property in it. But the system of tenures still exists. The statute of Charles II. only abolished military tenures and such parts of the feudal system as had become generally intolerable; but all lands in the kingdom are still held either by soccage tenure, into which military tenures were changed, or else by the respective tenures of frankalmoyne, grand serjeanty, and copyhold, which were not affected by the statute.

Some of the consequences of tenures, as they at present subsist, cannot be more simply exemplified than by the rules as to the Forfeiture and Escheat of lands, both of which, however, have undergone modifications since the statute of Charles II.

To attain a comprehensive and exact view of the present tenures of landed property in England and their incidents and consequences, it would be necessary for the reader to enter upon a course of study more laborious and extensive than is consistent with pursuits not strictly legal. Still a general notion may be acquired of their leading characteristics by referring to several of the articles already quoted, and to such heads as Attainder, Baron, Copyhold, Courts, Distress, Estate, Lease, Manor, Tenures, and such other articles as may be referred to in those last mentioned.

The notions of loyalty, of honour, of nobility, and of the importance, socially and politically, of landed over other property, are the most striking of the feelings which may be considered to have taken their birth from the feudal system. These notions are opposed to the tendency of the commercial and manufacturing spirit which has been the great moving power of the world since the decline of strict feudalism; but that power has not yet been able to destroy, or perhaps even very materially to weaken, the opinions above mentioned in the minds of the mass.

We are not, however, to pass judgment upon feudalism, as the originating and shaping principle of a particular form into which human society has run, simply according to our estimate of the value of these its relics at the present day. The true question is, if this particular organisation had not been given to European society after the dissolution of the ancient civilisation, what other order of things would in all likelihood have arisen, a better or a worse than that which did result? Some assistance in settling this question might perhaps be obtained by comparing the history of society, from this date, in the feudal countries, with its history in those parts of Europe to which feudalism never reached,—France or England, for instance, with Denmark, Sweden, or Hungary.

As for the state of society during the actual prevalence of the feudal system, it was without doubt in many respects exceedingly defective and barbarous. But the system, with all its imperfections, still combined the two essential qualities of being both a system of stability and a system of progression. It did not fall to pieces, neither did it stand still. Notwithstanding all its rudeness, it was, what every right system of polity is, at once conservative and productive. And perhaps it is to be most fairly appreciated by being considered, not in what it actually was, but in what it preserved from destruction, and in what it has produced.

The earliest published compilation of feudal law was a collection of rules and opinions supposed to have been made by two lawyers of Lombardy, Obertus of Otto and Gerardus Niger, by order of the Emperor Frederic Barbarossa. It appeared at Milan about the year 1170, and immediately became the great text-book of this branch of the law in all the schools and universities, and even a sort of authority in the courts. It is divided in some editions into three, in others into five books, and is commonly entitled the 'Libri Feudorum;' the old writers, however, are wont to quote it simply as the Textus, or Text. But the great sources of the feudal law are the ancient codes of the several Germanic nations; the capitularies or collections of edicts of Charlemagne and his successors; and the various Coutumiers or collections of the old customs of the different provinces of France. The laws of the Visigoths, of the Burgundians, the Salic law, the laws of the Alemanni, of the Baiuvarii, of the Ripuarii, of the Saxons, of the Anglii, of the Werini, of the Frisians, of the Lombards, &c., have been published by Lindenbrogius in his 'Codex Legum Antiquarum,' fol., Francof., 1613. The best editions of the capitularies are that by Baluze, in 2 vols. fol., Paris, 1677, and that by Chiniac, of which, however, we believe only the first two volumes have appeared, Paris, fol., 1780. Richebourg's 'Nouveau Coutumier Général,' 4 vols. fol., Paris, 1724, is a complete collection of the Coutumiers, all of which, however, have also been published separately. All these old laws and codes, as well as the Milan text-book, have been made the subject of voluminous commentaries.

FEVER, CONTINUED. Under the name fever are included various diseases which are distinguished by some term prefixed to this word, as scarlet fever, inflammatory fever, yellow fever, continued fever, intermittent fever, remittent fever, and such like. There can be little doubt that this term fever has been applied to very opposite and different states of the system, and the only idea implied by the word is a certain continuity in the disease, and perhaps a tendency in the diseased processes to come to a natural termination. The term fever is however frequently applied alone to that group of diseases to which recent medical writers have applied the term "continued fevers." This expression continued distinguishes them more especially from the fevers called intermittent [Ague], remittent [Hydrocephalus], and yellow fevers. By some writers it is supposed that the various forms of continued fever are but modifications of that same state of the system in which intermittent, remittent, and yellow fevers come on. There is however good reason to believe that ague and remittent and yellow fevers arise from causes different from those producing continued fevers. Hence they are now regarded as distinct. Dr. Jenner, who has recently written on this subject, sums up the forms of continued fever in the following manner.

"*Febricula*—A disease attended by chilliness, alternating with a sense of heat, headache, white tongue, confined bowels, high-coloured scanty urine, hot and dry skin, and frequent pulse, terminating in from two to seven days, and having for its cause excess, exposure, over-fatigue, &c.—(*i.e.*) the cause of febricula is not specific.

"*Relapsing Fever.*—A disease arising from a specific cause, attended by rigors and chilliness, headache, vomiting, white tongue, epigastric tenderness, confined bowels, enlarged liver and spleen, high-coloured urine, frequent pulse, hot skin, and occasionally by jaundice, and terminating in apparent convalescence in from five to eight days; in a week a relapse—(*i.e.*) a repetition of the symptoms present during the primary attack. After death, spleen and liver are found considerably enlarged; absence of marked congestion of internal organs.

"*Typhoid Fever.*—A disease arising from a specific cause, attended by rigors, chilliness, headache, successive crops of rose spots, frequent pulse, sonorous râle, diarrhœa, fulness, resonance, and tenderness of the abdomen, gurgling in the right iliac fossa, increased splenic dulness, delirium, dry and brown tongue, and prostration, and terminating by the 30th day. After death enlargement of the mesenteric glands, disease of Peyer's patches, enlargement of the spleen, disseminated ulcerations, disseminated inflammations.

"*Typhus Fever.*—A disease arising from a specific cause, attended by rigors, chilliness, headache, mulberry rash, frequent pulse, delirium, dry brown tongue, and prostration, and terminating by the twenty-first day. After death, disseminated and extreme congestions; in young persons, enlargement of the spleen." ('Medical Times,' 20th Paper.)

We may take, for the convenience of describing the condition of the system in the state of continued fever, the ordinary continued fever of this country, the disease denominated Common Continued Fever (Synochus Mitior). The phenomena which take place in this disease, and the order in which they succeed each other, are the following:—

The first event in the series is the derangement of the functions of the nervous system. There is reason to believe that this derangement takes place primarily in the organic system of nerves, that system which presides over the nutrition of the organs, and consequently that the very first effect of the noxious agent, whatever it be, which produces fever, is to disorder the health of the organs, and thereby to impair their energy.

Though it is probable that a disorder of the organic nerves is the first event that actually takes place in fevers, yet the first event of which we become conscious would seem to be a derangement in the second portion of the nervous system, the great nervous centres in which sensation, intellectual operation, and voluntary motion have their seat, namely, the brain and spinal cord. The organic functions being carried on without consciousness, we can know that they are disordered only by their producing disturbance in some part of the sentient system. The organic portion of the nervous system is most intimately connected with the sentient portion, and any disorder of the former is quickly extended to the latter. In an attack of fever the disordered condition of the brain is indicated by a loss of mental energy. But this loss of mental energy, though it is probably the very first indication of fever of which any one can be conscious, is by no means the first symptom which usually attracts attention. In general the loss of mental power is not observed until it becomes distressing, which does not often happen until the progress of the disease is further advanced. The loss of mental power is indicated by the inability to perceive clearly the trains of ideas, and to attend closely to their relation; whence result indistinctness and confusion of mind, and the want of capacity to form a sound judgment.

As this state of the mind depends on the disordered condition of the organ in which the mind has its seat, the brain, and as the servant of the mind, volition, has its seat in the same portion of the nervous system: closely connected with this mental weakness, is the loss of energy in the muscles of voluntary motion. Lassitude is the result. The movements of the body are feeble and unsteady, as the energy of the mind is impaired.

From this morbid condition of the brain and of the muscles of voluntary motion, there results an uneasy sensation, of which no idea can be conveyed by words; it must be felt to be understood. It is not pain, it is more distressing than pain; even the mere restlessness which accompanies, and which forms so large a part of it, any one would gladly exchange for intense pain: it is this state which has been appropriately and expressly named 'Febrile Uneasiness.'

But very soon there is superadded to this uneasy sensation positive pain. In general pain is first felt in the back and loins, and in the limbs. It is rare that this symptom is absent in the commencement of this form of fever, and it often occasions more distress to the patient than anything else during the first stage of the disease.

The remaining part of the history of an attack of common continued fever has been thus given by a physician who has had the most abundant opportunities of witnessing the progress of the disease:—

Already a remarkable change is commonly visible in the countenance. Its expression is that of dejection; it is often strikingly similar to that of a very weak person suffering from fatigue. The colour of face is pallid, and the features are somewhat shrunk; but its general aspect is so peculiar and characteristic, that an experienced eye can distinguish the disease, even at this early period, and without asking a single question. The skin partakes in a remarkable degree of the debility which so early shows itself in the muscles of locomotion. This is indicated in a striking manner by its increasing sensitiveness to the physical agents by which it is surrounded, and by its inability to resist their influence. Ordinary degrees of temperature produce a sensation of cold which is sometimes intolerable; chilliness is felt even in a heated room, or in a warm bed; hence the sensation of cold, sometimes increasing to shivering, which has been considered one of the most constant signs of fever. But this feeling of chilliness by no means depends on external temperature: it is increased by cold, but it exists in spite of an elevated temperature; it arises from an internal cause, and is not to be counteracted by external heat.

While the patient experiences the sensation of cold, there is no diminution of the quantity of caloric in the system. The thermometer applied to any part of the body commonly rises as high as in the state of health; and the skin, touched by the hand of another person, communicates not the feeling of cold, but often, on the contrary, that of preternatural heat. There is no positive abstraction of caloric from the body, nor any failure in the process, whatever it be, by which animal heat is generated: there is only altered sensation, in consequence of derangement in the function of the skin. In this form of fever the chilliness in many cases never amounts to shivering; in others there is an attack of well-marked rigor, and in others, again, there is either no feeling of cold, or it is so slight that it escapes observation.

The symptoms now enumerated are all clearly referrible to derangement of the functions of the spinal cord and brain. There is as yet no affection of any other organ obviously or at least much developed. The circulating system, it is true, is just beginning to be affected. The pulse is no longer perfectly natural; it is more languid than in the state of health; sometimes it is also quicker; at other times it is slower; now and then it is scarcely changed in frequency, but its action is invariably weaker than in its sound state.

At the same time the respiration is affected in a corresponding degree; it is shorter and quicker than natural: the chest does not expand so freely, and compensation seems to be sought in an additional number of respirations. Oftentimes neither the pulse nor the respiration appears to be much altered, if the patient remain perfectly still; but if he rise and walk across the room the pulse instantly becomes rapid, and the respiration is quickened almost to fainting.

The transition from the affection of the nervous and sensorial to that of the circulating and respiratory systems is thus clear and striking. Physiology teaches us how closely these systems are connected, and how mutually they are dependant one upon the other, the closest observers and the ablest experimentalists candidly confessing that they are scarcely able to determine which is the least dependant, or the action of which is the least necessary to the other's performance of its functions. The nervous system being first deranged, it is thus consonant to what we know of the healthy function of the animal economy that the circulating and the respiratory systems should be the next to suffer.

How long the nervous system may continue thus deranged before any other organs are involved, excepting the circulating and the respiratory, to the extent just stated, is uncertain. There can be no doubt that in this mild form of fever the range of the duration of this isolated state of disorder, if we may so express it, is from a few hours to several days. The rapidity or the slowness with which other systems of organs become involved seems to depend very much upon the acuteness of the attack. In general, the more acute the fever, the more rapidly the individual phenomena succeed each other, and the entire series becomes complete. But this is not, and it is important to bear in mind that it is not, invariably the case, for experience teaches us that the severity and danger of the disease are not diminished by the slowness of its approach; and that cases occur which are slow in forming, and which do not for a while excite alarm, that ultimately become truly formidable.

It has been stated that the circulation languishes with the diminished energy in the sensorial faculties, and the loss of power in the muscles of locomotion. After a while the pulse, which was feebler than natural, becomes more full, more strong, and generally more quick than in a sound state; and now the skin, which was cold, becomes preternaturally hot. The previous cold consisted, for the most part, of altered sensation, there being little or no loss of caloric; but the feeling of heat, on the contrary, is the result of an actual increase of temperature: for the heat in the interior of the body, as well as on the surface, rises in some cases several degrees, as is ascertained by the thermometer, the range of increase being from the natural standard 98° to 105°, beyond which it is seldom found to augment in this form of fever. The heat is at first not uniform over the entire surface of the body: it often happens that some parts are cold while others are burning hot. The heat is oftentimes particularly intense over the forehead or over the back part of the head, or over the whole scalp, while the cheeks are commonly flushed. All these symptoms denote a morbid condition in the action of the heart and arteries. Since the generation of animal heat is so intimately connected with the circulating and the respiratory functions, it is probable that the increase of temperature is the result of some morbid action of the capillary vessels belonging to these systems. What the disordered action of these vessels is which produces increase of temperature we do not know; but the object of scientific observation is in some degree accomplished when it is ascertained that one condition of these functions is invariably connected with a morbidly diminished temperature; another with a morbidly augmented temperature; and another with the temperature of health.

Immediately the circulation is thus excited, the functions of secretion and excretion become deranged. The mouth is now dry and parched; the tongue begins to be covered with fur; thirst comes on; the secretion of the liver, probably also of the pancreas, and certainly of the mucous membrane lining the whole alimentary canal, is vitiated, as is proved by the unnatural quantity, colour, and fetor of the evacuations; the urine likewise is altered in appearance, and the skin is not more remarkable for the sense of heat than for that of dryness and harshness which it communicates to the touch. With the excitement of the pulse and the increase of the heat, the pain in the back and limbs, and the general febrile uneasiness are much augmented.

At this period, then, the fever is fully formed; the series of morbid phenomena is complete: anything more that happens is referrible to degree and to duration, and must be the result of one or other of these circumstances, or of their combined operation.

As soon as the preternatural heat comes on, pain begins to be felt in the head. The pain of the head is often slight at first, and occasionally it remains slight throughout the disease; at other times it is pretty severe. Cases sometimes occur, in which, instead of pain there is only a sense of giddiness, and now and then the uneasy feeling is described as that of lightness; or on the contrary, as that of heaviness, or weight. But whether the feeling be pain, and that pain be slight or severe, or whether it be giddiness or lightness, or heaviness, it indicates a similar condition of the organ and requires a similar treatment.

With the accession of pain of the head there is a manifest increase in the disturbance of the sensorial functions. The inability to think, to compare, to reason, to judge, great as it was at the commencement, is now much greater. Instead of being more dull, there are certain states of the mind which now become more acute and vigilant even than in health. Sensation itself, at this period, is invariably acuter than natural, as is indicated in all the organs of sense. The eye cannot well bear the light: there are few cases in which the full glare of day does not excite uneasiness, while in many the ordinary light of a room cannot be borne: in these cases the opening between the eyelids is frequently observed to be contracted, as if from an involuntary effort to exclude a portion of that stimulus which in health excites no inconvenience, and this state of the eyelids assists in giving to the eye its dull and heavy expression so characteristic of fever. The increase of sensibility in the organ of hearing is equally striking. Sounds which were not noticed during health become acutely and even distressingly sensible, while accustomed noises, such as that of a crowded street, are always painful and often intolerable. The skin, considered as an organ of touch, is in a like morbid state. An impression barely sufficient in the state of health to produce sensation excites the feeling of tenderness, and alternations of temperature which in ordinary states are scarcely perceptible are painful. The senses of taste and smell, on the contrary, are nearly obliterated, owing to the altered condition of the membranes upon which the sensitive nerves are distributed.

From the earliest attack of the disease the sleep is disturbed and unrefreshing; now scarcely any is obtained; the febrile uneasiness will not allow of repose, the patient cannot remain in any position long, incessantly shifting his place, never eluding his pain. At this stage the sense of uneasiness in the limbs, oftentimes the severity of the pain over the whole body, is peculiarly distressing.

With this progressive increase in the affection of the spinal cord and the brain, the derangement in the circulating system is proportionately augmented. The pulse is invariably altered, both in frequency and character, Generally it rises to 90, sometimes to 100; but in this form of fever it seldom exceeds this number; and occasionally it never rises above 80. The stroke of the pulse is usually stronger and fuller than natural, though it commonly retains its softness, and does not impress the finger with that sensation of sharpness which is characteristic of ordinary inflammation. Occasionally, however, a degree of sharpness may be perceived in it, and it is not easily compressed.

The thin white fur which already had begun to appear on the tongue progressively increases in extent and thickness. The colour of the fur usually changes as the disease advances, from a dirty white to an ash colour; but in this form of the disease the tongue always remains moist and never becomes brown. This state of the tongue is almost always accompanied with thirst, but it is never urgent. There is always a loss of appetite. The bowels are generally constipated, and the secretions of the whole alimentary canal are vitiated.

Thus we perceive that the progress of the disease consists in increasing mental and corporeal weakness; increasing pain in the back, loins, and limbs; increasing heat of skin, acceleration of pulse, and general febrile uneasiness, together with the occurrence of pain in the head, and progressive derangement in the functions of secretion and excretion.

The fever in this mild form is now at its height. It remains stationary, or at least with very little change, for an indefinite period, generally for some days. The cerebral affection does not increase beyond what has been described: there are no greater indications of disease in the respiratory organs, and the mucous membrane of the stomach and intestines does not denote any progressive advancement in disease.

In the great majority of patients in whom the symptoms continue thus moderate, the disease disappears about the end of the second week, that is, they are convalescent at that period; but it usually requires eight or ten days longer before they have regained sufficient strength to leave the sick chamber. Sometimes, although there is no greater severity in the symptoms, the disease is more protracted, and the recovery is not complete until the fourth or even the fifth week. Beyond this period it is very rare for this form of the disease to be protracted.

Almost all who are attacked with the malady in this its mildest form, recover: but now and then it happens that the symptoms go on with this degree of moderation until about the end of the second week. Then at the period when it is usual for convalescence to take place there is no perceptible improvement; the patients seem even to grow weaker; they lie more prostrate in the bed, and they are soon incapable of moving; still they complain of no pain or uneasiness, and it is not easy to detect any trace of disease in any organ; yet it is but too evident that they grow worse, and ultimately they sink exhausted. In these cases, on examination after death, it is commonly found that disease has been preying on some vital organ, although its presence could not be detected during life; and this termination of the milder type of fever rarely happens except in aged persons whose constitutions have been enfeebled by previous diseases, or worn out by the various causes which depress and exhaust the powers of life.

With an occasional exception of this kind, the disease in this form always terminates favourably; and the first indication of returning health is remarkably uniform: it is almost always marked by longer and more tranquil sleep. Instead of that restlessness which is so characteristic of fever, and which forms the most distressing part of it, the patient is observed to lie more still, and on waking for the first time from an undisturbed slumber, he often spontaneously says that he feels better. Better he may feel, for his febrile uneasiness is gone; the load that oppressed him is shaken off; he is a new being. The pain of the head and of the limbs is so much diminished, that often he cannot help expressing his thankfulness at the change. The countenance becomes more animated; its natural expression returns; the tongue begins to clean, and after this state of the system has continued for two or three days the appetite returns. While these favourable changes are going on the pulse usually sinks about ten beats below its highest point at the height of the fever; it is not uncommon, however, for it to remain quick during the entire period of convalescence; and for some considerable time it is easily excited on any movement of the body, or any emotion of mind. In some cases, on the contrary, when the attack has been very mild, it sinks considerably below the natural standard, and is intermittent, a sign which has been observed to be attended with a sure and steady convalescence. In the mean time the appetite becomes keener than natural; the strength gradually improves; and in a short time the patient is restored to his usual health and vigour.

The transition of a mild case of fever into a severe one, or the progress of a case severe from the commencement, is accompanied with or depends upon certain changes that take place in certain organs. These changes occur with great regularity; the organs in which they take place are always the same; and the symptoms by which they are denoted are uniform. The organs affected are the spinal cord, the brain, the membranes of both, the mucous membrane of the lungs, and the mucous membranes of the intestines. Other organs become affected in the progress of the malady, but these are the organs which in a greater or less degree are invariably diseased, and which therefore must be considered as the true seats of the structural changes that take place in the regular course of fever. Accordingly in all the severer cases, the symptoms, which are only the external indications and expressions of the successive changes that take place in the internal organs, have their seat either in the head, in the thorax, or in the abdomen. Mixed and blended as these symptoms appear in the different cases which the practitioner is actually called upon to treat, they seem so complex and variable as to bid defiance to any arrangement: when analysed, nothing is more remarkable than their simplicity and their uniformity.

Previous to the changes of structure that take place in the internal organs, it is probable that the different fluids undergo changes no less important. There is indeed a controversy whether the very first change that takes place does not take place in the fluids, and more especially in the blood. There cannot be a question that a morbid change takes place in the blood at a very early period of fever; that that change is different at different stages of the disease; that it is essentially different according to the particular type of fever, and that it is always great in proportion to the severity of the attack. Without entering here into the controversy whether the very first event in the series be a morbid change in the blood, it is manifest that this fluid cannot but become diseased in the progress of fever, because all the processes by which the depuration of the blood is effected are disturbed, and consequently matters which it is the office of these depurating organs to remove from the circulating mass accumulate in it. Moreover there is evidence that the constitution of the blood itself becomes deranged, and that the natural proportions of its essential constituents are subverted. Of course, in a state of the system in which the most important secreting organs are diseased, and in which the fluid that affords the common materials from which the secretions are elaborated is also diseased, the secretions themselves must necessarily become vitiated.

Although these general symptoms are found more or less in all the forms of continued fever, there are some which are regarded as diagnostic of the special forms mentioned above that are of the highest interest. Thus it is found that the two latter forms, typhoid and typhus fevers, are attended with eruptions of the skin as essentially distinct as those of measles and scarlet fever. The eruption in typhoid fever consists of rose-coloured spots which consist of slightly elevated papula or pimples. Their apices are neither acuminated nor flat but invariably rounded, and the bases gradually pass into the level of the surrounding cuticle. These spots disappear completely on pressure, and resume their usual appearance when the pressure is removed. They leave no stain, or pit, or mark behind, and vary in size from a line to a line and a half in diameter. Each papula lasts three or four days, and fresh crops appear every day or two after their first eruption. These spots usually occur on the abdomen, thorax, and back, and only occasionally on the extremities. They usually appear between the seventh and fourteenth day of the disease. (Jenner.)

The rash of typhus fever is distinguished by its mulberry colour. On its first appearance it consists of very slightly elevated spots of a dusky pink colour; each spot is flattened on the surface, irregular in outline, and with no regular margin, but passing gradually into the colour of the skin. It disappears completely on pressure. The spots are of various sizes, and as they grow older do not entirely disappear on pressure, but a stain of the cuticle remains to indicate where they are. This eruption usually appears from the fifth to the eighth day of the disease, and subsides between the fourteenth and twenty-first days. These rashes must not be confounded with "miliary" vesicles, or "sudamina," which sometimes come on in these fevers.

As already indicated in the definitions of these fevers, the typhoid form is attended with a diseased condition of the mucous membrane of the bowels, and the small glands (Peyers) are affected. The symptoms of this disease correspond to this condition. In the early stages abdominal pains and diarrhœa set in, which continue to increase. The belly enlarges as in mesenteric disease, and is resonant on percussion. During the third week of the disease these symptoms become more formidable, and the stools amount to from five to ten in the course of the day. One of the most alarming symptoms is hæmorrhage from the bowels, which occurs towards the end of the attack. This is one of the most formidable symptoms of the disease, although not always attended with fatal results. These symptoms differ very much from those which occur in typhus fever, where there is generally obstinate constipation.

Fever then is a malady in which disease is simultaneously established in the most important organs both of the organic and of the animal life, in the vital fluid which nourishes and stimulates the whole system, in the excretory processes by which the purity of the blood is preserved, and in the secreting processes by which all the different tissues and structures of the body are formed. That it should be always a dangerous disease is therefore not wonderful, but the real extent in which it is the instrument of death is not generally known. Taking together the whole class of febrile diseases, and including the ravages committed by them at all seasons and in all parts of the globe, it is estimated that of the deaths that take place in the human race one half is always produced by these maladies.

With regard to the causes of continued fevers considerable differences of opinion exist. Some writers are inclined to the opinion that there are no specific causes of these forms of disease, but that wherever animal and vegetable matters exist in a state of decomposition, there any one of these diseases may be engendered according to the predisposition of the individual attacked. These writers even deny that there is a poison generated in the body capable of producing a disease in another body. Another body of observers believe that these fevers may originate in external causes, but that they are all of them capable of producing a poison—a materies morbi—which is capable of producing the disease in unaffected individuals. Whilst again, recent investigations seem to point out that typhoid fever is more especially dependent on decomposing animal and vegetable matters, writers supporting this view have called the disease *pythogenic* or drain fever. It is very certain that this form of fever is more liable to break out locally than typhus. It appears, however, to be communicable by the poison generated in the body, but not so much so as typhus.

With regard to typhus fever, it is asserted that it is alone maintained and propagated by a special poison like small pox and scarlet fever. Whatever may be the real causes of these forms of disease, all opinions point to the same means for the prevention of these diseases. Wherever fever has broken out, all sources of corruption should be removed. Drains should be cleansed, and foul deposits of every kind should be got rid of. In order to preserve others, the rooms of the sick should be well *ventilated*, the linen should be washed, and every precaution taken to prevent the discharges from the patient from coming in contact with others. Chlorine and other disinfectants may be advantageously employed. The patient should be *separated* as much as possible from others, and the poison from his body should have every chance of dilution by the free access of pure air.

The *treatment* of these diseases must depend very much on the nature of the case. There is no cutting short the progress of a fever by medicines, and when the disease is progressing favourably little else need be done than to attend to the dietetic wants of the patient.

In typhoid fever the state of the bowels forbid any but the most gentle of purgatives, and that only in the beginning of the disease. A saline treatment so often adopted for typhus is forbidden here. In sinking and exhausted states, ammonia, wine, and brandy are powerful agents for good. Quinine has been strongly recommended in all forms of continued fever by some writers, but Dr. Bennett, of Edinburgh, doubts its value in the fevers of Edinburgh. The various complications of the brain and respiratory system, in the course of the disease, require remedies adapted to meet the special symptoms.

(Sydenham's works; Mead, *Short Discourse concerning Pestilential Contagion, and the Methods to be used to Prevent it*; Sir John Pringle, *Observations on the Nature and Cure of Hospital and Jayl Fevers, in a letter to Dr. Mead: and Observations on the Diseases of the Army*; Clutterbuck *on Fever*; Southwood Smith, *Treatise on Fever*; *Philosophy of Health*; Copland, *Dict. of Practical Medicine*, *Cyclopædia of Practical Medicine*; Watson, *Lectures on the Practice of Physic*; Aitken, *The Science and Practice of Medicine*; Jenner *on the Identity or Non-identity of Typhus or Typhoid Fever*; Jenner *on the Diseases commonly confounded under the term Continued Fevers.*)

FEVER, YELLOW, a disease of frequent occurrence on the eastern and western coasts of America, in the West Indies, in Africa, and in Europe on the southern shores of Spain. The prevalence of this disease in these countries, its great fatality, and the mortality it produces in navies and armies, have attracted much attention towards it both from governments and medical men. This disease has been described under other names, such as typhus icterodes, Bulam fever, bilious remitting fever, vomito negro, vomito prieto, endemial casus, mal de grain, &c. Although this disease has a very distinct history, and can be easily distinguished by the mass of symptoms it presents, yet it is difficult to give in a few words anything like a satisfactory definition. Dr. Gillkrest, one of the most recent writers on this subject, gives the following definition: a disease in which "yellowness of the skin, partial or general, and towards the fatal termination, vomiting of a black or dark brown fluid, are frequent though by no means constant occurrences." Such a definition would be of little use for distinguishing the disease, and perhaps after all it will be found that yellow fever is only a modification, under peculiar circumstances, of some primary form of disease in which all fevers originate. It is certain that this disease has many symptoms in common with other fevers, and that it assumes the types of the common, continued, remittent, and intermittent fevers.

It has only been within a comparatively recent period that this disease has attracted much exclusive attention, and on this account some writers regard this disease as one altogether of modern origin, and fix the date of its generation during the latter part of the eighteenth century. But although no accurate account of this disease as distinguished from other fevers exists, previous to its appearance in the island of Granada, in 1793, yet there can be no doubt that the records of the occurrence of destructive fevers in those districts in which the yellow fever now occurs, refer to the same disease.

The attack of yellow fever is mostly preceded by well-marked premonitory symptoms. For two or three days previous to the attack there is a depression of spirits and an unnatural inactivity without any sufficient accountable cause. There is sometimes nausea, with a creeping chilliness, and pains in the loins, back, arms, legs, and head. The eyes are suffused, dull, and heavy, and the sight is dim and sometimes double. There is often slight confusion of mind and a kind of drowsy restlessness. The appetite is bad, the taste is perverted, and the bowels are either confined or relaxed. The skin is in some cases permanently dry, or there may be sweating after slight flushes of heat. The pulse varies considerably; it may be small, quick, and irregular, or soft and full. Such symptoms do not however always occur, and sometimes the patient is seized immediately with a shivering, the indication of the near approach of the worst symptoms. Sometimes during this premonitory stage there may exist a yellowness of the eyes and of the skin, and also a vomiting of bilious matter.

The commencement of the febrile attack mostly takes place at night: after the shivering, a state of general excitement takes place, which sometimes increases to a very distressing and unmanageable extent. Pains occur in the head, in the eyeballs, in the back and loins, and cramps in the gastrocnemic muscles. The patient prefers the recumbent position and lies upon his back, but is in a state of great restlessness, frequently throwing his arms about, more especially above his head. The face is usually flushed, sometimes of a crimson hue, and occasionally swollen so as to appear bloated and heavy. The eye has a heavy drunken appearance, is injected, swollen, and moistened with tears; the pupil is generally permanently dilated, and the balls seem protruded as if they would start from their sockets. The skin is in most cases flushed, dry, and warmer than natural. The pulse is accelerated, soft, full, and compressible; in some cases, however, it is unusually slow, and under these circumstances the skin is unnaturally cool. The tongue is swollen and coated with a white mucous paste. Vomiting does not often occur in this stage. The bowels are frequently more or less constipated, but easily acted on. The intellectual functions are more or less deranged. These symptoms last for twelve or thirteen hours, when the second stage may be said to commence. The general excitement now gives way to depression. The countenance becomes deeply expressive of anxiety. The congested state of the eye begins to yield, and in its place a slight yellow tinge is observed. This goes on increasing till it extends down the alæ of the nose and around the mouth. As the disease advances, in most cases the yellow tinge spreads itself over the whole skin, giving to the whole body, according to the complexion or temperament, various colours, from a pale lemon to deep orange or saffron colour. The pulse becomes slightly lessened in frequency. The coating on the tongue becomes yellow, and this organ towards its roof and at the edges and tips has a clean and dry red appearance. The stomach now becomes irritable and painful on pressure. Food is immediately rejected. There is a distressing sensation of internal heat. The vomiting is sudden, and not accompanied with any severe retching. The matters vomited are generally ingesta and a clear fluid, and only sometimes is bile discharged. The alvine secretions are mostly natural. The urine is diminished in quantity, and very yellow. There is frequent sighing of a deep and prolonged character. In malignant cases the breath exhaled has an acid odour. The intellectual functions are much affected, and the patient is in a state of low muttering delirium, or comatose. Sometimes petechiæ and miliary vesicles occur in this stage. In this state the patient may remain from two to seven days. The countenance then becomes more collapsed, the eye loses its full and prominent character, dark-coloured blotches and petechiæ occur on the body, the pulse becomes small and thready, the tongue loses its coating and becomes bright red, thirst becomes urgent, and there is lastly the vomiting of a dark and mucous-looking fluid, which has been called the "black vomit," and has in fact given the name sometimes to this disease. This symptom, however, does not always occur. As death approaches the exhaustion becomes greater, the respiration is hurried and noisy, the surface and extremities become cold, and covered with a general clammy perspiration. In some the last moments are marked with great pain and strong convulsions, whilst in others death seems to come upon the patient unawares.

These general symptoms are by no means presented in every case, some having been constantly observed by one medical writer, whilst others have never witnessed them at all. Amongst the forms which this disease assumes, three are mentioned by some writers as pointing out important differences in the character of the disease: these are called inflammatory, adynamic, and malignant. The *inflammatory* occurs in full plethoric habits, and the whole of the symptoms indicate a greater amount of excitement and activity, and the disease proceeds to a fatal termination sooner. The *adynamic* variety occurs in those who have deficient animal vigour. In this form of the disease the pulse is slow, the skin cold and clammy, no resistance appears to be made to the progress of the disease, and the patient sinks in the course of four or five days. The *malignant* form is the worst of all: from the first the patient seems attacked with death; all the symptoms are low from the beginning, and no reaction is established. Persons seldom recover from this state, and many die during the first twenty-four hours of the attack.

The nature and origin of the black matter which is so often vomited in cases of yellow fever has been the subject of much investigation. The most correct view is probably that of Dr. Fordyce, who considered that it was identical with the incrustation of the tongue, gums, and lips found generally in violent fevers, and that probably this is an exudation thrown out from the surface of the stomach, or even from the duodenum and jejunum. When collected and given to animals it produced no bad effect upon them, and an atmosphere impregnated with its exhalations does not appear to be injurious. Under the microscope it has the appearance of minute scales of smoked mica, being of a dark brown or red colour. It is probably nothing more than the globules of blood broken down, which have oozed through the surface of the mucous membrane, instead of the ordinary secretion, and perhaps under the influence of the violent vomiting. It may frequently be mixed with bile, but it does not appear in the majority of cases to have the character of bile at all.

As it is difficult to give a definition of yellow fever, so is it difficult to give any rules by which it may be distinguished in individual cases from other diseases. Its occurring, however, generally in several individuals at the same time, soon leads to the development of the group of symptoms which we have described, and by which it may be distinguished from allied diseases.

The mortality from this disease is always very considerable. It is usually much greater at the commencement of the epidemic than it is at subsequent periods. In some instances all the cases occurring for the first few days after the breaking out of the fever have proved fatal. Sometimes however the disease is very mild, and but few fatal cases occur. The mortality is generally greatest amongst the young and robust, and this will perhaps account for its fatality amongst soldiers and seamen. This fever has been regarded as peculiar to places between 40° N. lat. and 20° S., and requires a climate in which the mean summer range is not less than 75°, or, according to some authors, 80°. More temperate climates are not, however, free from its attacks. It appeared at Lisbon in 1857. One-twelfth of the whole population was attacked with the disease, and of these one-third died. The total of the deaths in the whole population was between five and six thousand. From the histories of this attack in Europe, we may learn that none of our towns have an immunity from this disease, and that it is only by carrying out those sanitary measures which are now so extensively adopted, that we can expect to be free from such a visitation of this disease as at Lisbon.

The morbid appearances of the body after death do not throw any light on the nature of this disease. In the head the dura mater is found studded with dark-coloured spots; under the arachnoid is frequently accumulated a yellowish serosity. The lesions in the chest are not remarkable. The stomach is generally distended with air, its mucous surface is occasionally suffused with blood, and its vessels are generally gorged with blood. The orifices of numerous canals may be seen, from which by slight pressure oozes a fluid which appears to be the "black vomit." The small intestines participate in some measure in the lesions of the stomach. The liver is sometimes engorged with blood, and sometimes it is hard and dry. The spleen is usually increased in volume and softened.

In the treatment of yellow fever much difference of practice has prevailed, according to the opinions of those called upon to treat the disease; and unfortunately that kind of evidence does not at present exist on which we could rely with regard to the value of any particular course of treatment. Under these circumstances the judicious practitioner will act on general principles, and treat whatever cases come before him according to the symptoms they present. As is mostly the case in the treatment of fevers which in their course exhibit both active and low symptoms, two very different plans of treatment have been recommended; the one antiphlogistic, the other stimulant. Without discussing the respective merits of these plans of treatment, it may be stated that both may be rendered necessary in different stages of the disease.

Amongst antiphlogistic remedies, blood-letting has been highly commended, but it is not so frequently employed as formerly. The next remedy in importance is mercury. Some of the best writers on yellow fever, and those who have had the largest experience, consider mercury as their sheet-anchor in this disease. It should be administered in doses of sufficient quantity to affect speedily the mouth. Many practitioners who use this remedy do not employ blood-letting as an ordinary remedy, but only in those cases in which the inflammatory symptoms preponderate. In addition to these means, purgatives, emetics, antimonials, and cold affusion have had their advocates. These remedies are however all of them adapted more to particular states of the system than to the disease of yellow fever, and should be administered according as circumstances arise which may indicate their necessity. In cases where the disease assumes a remittent form, quinine may be administered with advantage. Dr. Stevens particularly insists on the administration of saline medicines in yellow fever, to which there is no objection, provided the stomach will retain them, and they probably have a beneficial effect on the system according to his theory.

Of all the questions connected with yellow fever, perhaps that which regards its *cause* has been discussed with the most zeal and bitterness. We cannot here go into any details of this discussion, but the great point in dispute is the contagiousness of this disease. Many of the early writers on yellow fever concluded that it was contagious, and on this account persons who have been exposed to its influence are obliged to submit to the most rigid quarantine regulations. But whilst there is much evidence to prove that this disease is communicable by a morbific matter generated in the human system in a state of disease, there can be no doubt that it has in most cases a local origin. Many recent writers have supposed that the local cause of this disease was to be found in the temperature and other atmospheric phenomena in the district visited by the disease; but this cause is too general to account for the exceeding local character of the disease in many instances. Cases are recorded in which the inhabitants of particular parts of a town, the one side of a street, or even one room of a house, have been attacked, whilst all others have escaped. The true theory of the production of these diseases is probably to be found in the fact that they originate in decomposing animal and vegetable matter, and afterwards become susceptible of communication from one individual to another by a poison generated in the body. The history of the development of the disease at Lisbon is remarkably confirmatory of these two points.

(*Library of Practical Medicine*, article "Yellow Fever," by Dr. Shapter; *Cyclopædia of Practical Medicine*, article "Yellow Fever," by Dr. Gillkrest; Bancroft, *An Essay on the Disease called Yellow Fever;* Dr. R. D. Lyons, *Report on the Yellow Fever at Lisbon, in* 1857.)

FIBRIN. Fibrin is an important constituent of animal and vegetable organisms. In animals it occurs dissolved in the blood, to the extent of 2½ parts in 1000, and is the principle of which muscle and the fibrous tissue of flesh are built up; indeed, these parts are usually looked upon as consisting of fibrin itself, though altered in several respects from the condition in which it exists dissolved in blood: the name also is derived from the fibrous character of these tissues, particularly from the bundles of fibres composing the muscles.

Fibrin has already been shortly noticed under the article ALBUMEN, as forming, with a few other closely allied substances, that interesting class of bodies known as the protein or albuminoid group; they are sanguigenous or blood-forming matters, and hence are usually termed *plastic materials of nutrition*, to distinguish them from those constituents of food that serve to maintain the function of respiration only, and hence called *respiratory* elements. The lean part of meat contains large quantities of fibrin and other plastic materials, obtained in the first instance from certain parts of plants, and stored up, as it were, in a concentrated form for the use of man; while the fat of meat, together with such respiratory principles as sugar, starch, &c., serve to keep up the heat of the body by the gradual oxidation or slow burning they undergo during the process of respiration.

Fibrin undergoes spontaneous coagulation very soon after its removal from the living structure. Thus, blood freshly drawn from an animal is tolerably fluid, but after standing a short time becomes transformed into a gelatinous mass or clot; this is owing to the alteration of the fibrin from the liquid to the solid state. Again, the recently expressed juice of vegetables soon deposits a precipitate from a similar cause. This property of spontaneous coagulation is alone possessed by fibrin, and serves therefore to distinguish it from its congeners, albumen and casein.

1. *Animal fibrin* is most readily obtained from blood; it is, however, contained in some quantity in chyle and in lymph. To obtain it, fresh blood is briskly whipped with a bundle of twigs, when, after a short time, the fibrin, in the form of short elastic strings, is found adhering to the twigs. It is still contaminated with some of the red colouring matter of the blood, but by maceration in, and patient washing with water, it is finally obtained quite colourless. When dried, this fibrin has a horny appearance, is hard, opaque, of a grayish or yellowish colour, and without taste or odour. It is insoluble in cold water, alcohol, or ether, but by long contact with boiling water is to a certain extent decomposed. Heated with water in a sealed tube to 300° Fahr. it entirely dissolves, forming a solution precipitable by acids, and much resembling the solution of albumen obtained under similar circumstances. A somewhat analogous solution occurs if the fibrin, in contact with a little water, is exposed to the air for some time; but in this latter case a considerable amount of decomposition occurs, and sulphide of ammonium, butyric acid, leucin, and other principles are generated. Animal fibrin is soluble in moderately dilute solutions of the fixed caustic alkalies, yielding a liquid possessing the properties of albuminate of the base; acetic or tribasic phosphoric acids precipitate the fibrin, but in excess redissolve it. The fibrin may also be made to combine with other metallic oxides; the resulting compounds are, however, almost identical with the albuminates. Digested in strong sulphuric acid, fibrin swells up, and by aid of a gentle heat entirely dissolves. Hot nitric acid also dissolves it, the solution containing *xanthoproteic acid*, an acid that is also produced under similar circumstances from albumen and casein. Hot concentrated hydrochloric acid decomposes fibrin into leucin, tyrosin, and other matters.

Epidermose is the name given by M. Bouchardat to that part of the fibrin obtained from blood, that is not soluble in dilute hydrochloric acid; that chemist considering it to be identical with a substance which forms the base of the epidermis: while to the portion of the fibrin that is dissolved by the dilute acid he gives the name *albuminose*. According to Liebig, however, blood-fibrin swells up in dilute hydrochloric acid, but does not form a true solution at all; while muscle-fibrin dissolves more or less completely in that menstruum.

Fibrin has been examined and analysed by several chemists with tolerably uniform results, but though its composition has been thus ascertained, its true constitution is not at present satisfactorily established. Mulder, who has paid considerable attention to this and the analogous azoto-sulphurised principles, gives the following as the percentage composition of fibrin:—

Carbon	52·7
Hydrogen	6·9
Nitrogen	15·4
Oxygen	23·5
Sulphur	1·2
Phosphorus	0·3
	100·0

The combustion of fibrin is always attended with a residue or ash, containing phosphate of lime and a little phosphate of magnesia.

2. *Vegetable fibrin* is frequently met with in pharmaceutical operations on the newly-expressed juice of fresh vegetables, nearly all such liquors depositing coagulated fibrin on standing for a short time. Like animal fibrin it does not admit of being examined in the liquid state, but in the solid form is obtained in what is generally considered to be a more or less pure state, from the so-called gluten of wheat flour. Boiling alcohol dissolves a considerable portion (true gluten) of this gluten, and what remains undissolved after repeated ebullition with the alcohol and with ether, is vegetable fibrin. Its ultimate chemical composition is very much the same as that of animal fibrin. In contact with moisture it is slowly decomposed. A farther description of its characters and properties is unnecessary, inasmuch as, so far as those characters are known, it would be but a reiteration of what has already been detailed above under *Animal Fibrin*.

FIBRÖIN. This name has been applied by Mulder to the nitrogenous substance composing the fibre of silk. It is purified by treating raw silk successively by boiling water, alcohol, ether, and acetic acid. It then contains:—

Carbon	48·53
Hydrogen	6·50
Nitrogen	17·35

FIBULA, a term used among the Romans for the brooch or buckle with which their vests were usually fastened. It is derived from *figo*, "to fix," and the most ancient form of the word is supposed to have been *figibula*. These fastenings were made in very great variety, both as to material and form, and were sometimes decorated with engraved stones or gems, for like the modern brooches, fibulæ were employed for ornament as well as use. Fibulæ of gold were often used as presents. The most common were made of brass or iron. The most usual was that of a circular ring or disc of metal, with a pin moving on a hinge, and passing across the centre of the circle. Fibulæ were used by the Roman women for fastening the inner and outer garment (*indutus* and *amictus*), and the scarf or cloak; sometimes indeed they not only wore them for these purposes on their breast and one or both shoulders, but in the later and more luxurious ages as ornaments down their sleeves, and for fastening their tunics above the knee. Count Caylus, in his 'Recueil,' pl. 110, fig. 4, has engraved a fibula which served the double purpose of a fastening to the garment and a key. The richly ornamented buckles used by the Romans for fastening the belt and girdle were also called *fibulæ*. *Fibula* was a term likewise applied by the ancients to the iron brace or band used for joining or fastening beams, mentioned by Cæsar ('De Bello Gall.,' l. iv., c. 17) and described by Vitruvius (l. i., c. 5). The *fibula chirurgica* was an instrument used by surgeons for drawing the lips of a wound together, noticed by Pitiscus, in his 'Lexicon,' p. 778, who also mentions the *fibula gymnastica*, sive *theatralis*, "quæ cantoribus et comœdis inserviebat," particularly described by Celsus, and several times alluded to by Juvenal and Martial. This was a ring of light workmanship.

FICHTELITE, a fusible volatile crystalline substance, found in the submerged pine-trees of the Fichtel-gebirge. Its composition is $C_{20}H_{20}$.

FICTION. [NOVEL; ROMANCE.]

FICTIONS (in Law) have been somewhat quaintly defined to be "those things that have no real essence in their own body, but are so acknowledged and accepted in law for some especial purpose." These especial purposes are various. The law, it is said (by which we must understand those who for the time are the interpreters of it), shall never make any fiction but for necessity, and in avoidance of a mischief. (Coke's 'Rep.,' iii. 30.) This is as much as to say that those who interpret the law will, in order to avoid a special hardship, or remove some unexpected difficulty not provided for by the law, resort to a fiction; that is, they will imagine something to be which is not. It is said that such fictions have always a good end in view; that is, an end considered good by those who make or maintain the fictions. It was wisely said, that fictions of law must not be of a thing impossible; but the reason is rather curious, "for the law imitates nature." If we object to the soundness of the reason in the instance last mentioned, we cannot but approve of the following rule as to fictions: that a man could never be subject to the penalty of a statute by a fiction of law. The law, it was said, would also make fictions in order to avoid absurdity; but this could hardly have been said in earnest.

Blackstone shows by what fiction the Court of Queen's Bench originally held pleas of all personal actions: "It being surmised that the defendant is arrested for a supposed trespass which he never has in reality committed; and being thus in the custody of the marshal of the court, the plaintiff is at liberty to proceed against him for any other personal injury: which surmise, of being in the marshal's custody, the defendant is not at liberty to dispute." Such liberty of disputing the fiction would clearly spoil the whole business, and was therefore as necessarily disallowed as the fiction was allowed. (See also the fictions formerly resorted to in EJECTMENT, and in the Court of EXCHEQUER.) Of the same kind is the fiction mentioned by Blackstone, by which a contract made at sea is feigned to be made at the Royal Exchange, or other inland place, in order to draw the cognisance of the suit from the courts of Admiralty to those of Westminster Hall. "Such fictions," as Blackstone remarks, "are adopted and encouraged in the Roman law: a son killed in battle is supposed to live for ever for the benefit of his parents; and by the fiction of *postliminium* and the *lex Cornelia*, captives, when freed from bondage, were held to have never been prisoners; and such as died in captivity were supposed to have died in their own country."

Fictions in law, though often ridiculous enough, have generally had their origin in some defect in the existing laws or course of procedure, and have pointed out in what respects the judges or interpreters of law, and, as we may suppose, general opinion also, under the influence of which judges must to some extent be, have felt that change was necessary. Many fictions, so far from being injurious, have been beneficial; but it must be remarked that they are the indications of a rude state of social organisation, and must gradually disappear with the improvement of the institutions of society; for their existence supposes a defect which it is the business of legislation to remedy.

FIDDLE. [VIOLIN.]

FIDEI COMMISS. According to German civil law, the fidei commiss is intimately connected with the law of inheritance among the nobility, being the regulation according to which the whole or part of a family property is enjoyed by a certain member of the family, on the condition of leaving it unimpaired to the person pointed out by the particular family arrangement; either to the first-born male, when it is called *majorat;* or to the last-born male, when it is called *minorat;* or to the oldest member of the family without regard to direct descent, when it is called *seniorat.* Like the English law of entail, the object of this institution is to render the family property inalienable; it may however be mortgaged, but this is merely a temporary sequestration of the revenues which are applied to cancelling the debt. In modern times, this institution, like many others, has been abolished in some parts of Germany, partly by the introduction of the French law, as in the Rhenish provinces, and partly by the amalgamation of the former German civil law with the Code Napoleon, as in Bavaria. In the north of Germany, however, where the ancient Saxon law was prevalent, as in Hanover, Saxony, and other countries, it has been maintained, and is still in force.

FIDEICOMMISSUM, or a transaction dependent upon honour and probity (*pudor*) rather than legal sanction (*vinculum juris*), I. 2. 23, 1, in the Roman law, is something given by will or codicil, not directly to the person beneficially interested in it, but to some other person, with a request that he will transfer it to the party for whom it was intended. The person thus intrusted was called Heres Fiduciarius; and the person for whom it was intended Heres Fideicommissarius. It was necessary that an heir (*heres* in the Roman sense) should be named, or no property could be transmitted to the fideicommissarius; for, without the "institutio heredis," the will itself was invalid, but a fideicommissum might be left by an intestate in the manner prescribed in the Institutes 2. 23, 10. (Gaius, ii., 248, &c.) Originally it entirely depended on the good faith of the trustee (*fiduciarius*) whether he performed the will of the testator or not.

The origin of these fideicommissa probably was in a desire to evade the strictness of the old civil law; as we see in the case of Q. P. Rufus (Val. Max., iv. 2, 7), who, being an exile, was incapacitated from taking a gift under the will of a Roman citizen, but yet could claim it from his mother, to whom it had been given in trust for him. (See also Cic. de Fin., ii. 18, § 58; and Quintil. Declam., 325.) Gaius, however (Comm., ii. 285), attributes the origin of these testamentary injunctions to the capacity of the peregrini to receive bequests in this way; but he gives no account of the time when, or the mode in which, such capacity was obtained. In the time of Augustus the rights of the fideicommissarius became legally established by the emperor giving the consuls jurisdiction in such matters. Afterwards pretors were expressly appointed, under the name of Prætores Fideicommissarii, to take cognizance of such trusts, but the consuls still retained their jurisdiction also. (I. 2. 23, 1.) In the provinces the governors (*præsides*) took cognizance of fideicommissa. (Ulpian, 'Frag.,' 25, 12.) Fideicommissa, or trusts of specific things, became gradually assimilated as to their qualities and incidents to legacies. The following remarks apply to fideicommissa where the whole inheritance (*hereditas* in the Roman sense), or a determinate part, was given to a trustee in trust.

By the old Roman law, the *heres* who was the successor in universum jus defuncti, on taking possession of the testator's property, became liable to all his debts and obligations, and consequently those who only took the property as trustees (*heredes fiduciarii*) often refused to encumber themselves with a burden from which they could derive no advantage, and might sustain great loss. To remedy this inconvenience, it was enacted by the Senatusconsultum Trebellianum, passed in the time of Nero, that when the trustee had given up the property to the fideicommissarius (*cestui que trust* of the English law), all right of actions by or against the trustee, in respect of the property, should be transferred to the cestui que trust. (I. 2. 23, 4 & 6.)

If the trustee refused to accept the inheritance, the pretor, on the petition of the cestui que trust, could compel him under the Senatusconsultum Pegasianum, passed in the time of Vespasian, to accept and to transfer the property to his cestui que trust, who took it with all its burdens. No particular form was requisite in order to effect this transfer. (I. 2. 3, 5, and 6.)

By the Senatusconsultum Trebellianum, if the heres was required to transfer not more than three-fourths of the inheritance to the cestui que trust, the two parties were liable to all suits and burdens in respect of the property according to their several shares. If he was required to transfer more than three-fourths or the whole, the S. Pegasianum allowed him to retain one-fourth, as the Falcidian law did in the case of legacies. If the heres let himself be compelled to accept the trust under the S. Pegasianum, he lost his one-fourth. (D. 36, 1.)

The cestui que trust was himself sometimes only a trustee for others, and in this case never had the benefit of the one-fourth: the same was the case if a legatee had to transfer a legacy to another.

In his remarks upon the origin of Uses and Trusts in England, Mr. Spence has given a short but clear and able sketch of the introduction of fideicommissa at Rome; and in a note to that part of his text which treats of the technical terms necessary to constitute a fideicommissum, he states "that these forms of expression are constantly referred to as guides to the Court of Chancery on questions of the like nature." Vide int. al. "Knight *v.* Knight," 3 Beavan, 161 & 172.

(Spence's *Equitable Jurisdiction of the Court of Chancery*, vol. i., p. 438.)

FIEF. [FEUDAL SYSTEM.]

FIELD (in Magnetism), is the space between the two poles of a magnet, where the two forces mutually re-act. [MAGNETISM.]

FIELD (in Optics), is the actual magnitude of the space that can be presented at once to the eye of the observer; it must vary with the magnifying power, and is large in proportion as this is small. With the lowest class of powers it is a circular space not exceeding the eighth or the tenth of an inch in diameter. With the power of 500, the field is only 1-70th of an inch in diameter. [MICROSCOPE.]

FIELD-GLASS. Between the object-glass and the eye-glass of a microscope there is usually interposed a convex lens, which receiving the diverging rays from the former before they form an image, has the effect of contracting the dimensions of the image and increasing its brightness, so that it is not too large or indistinct to be seen at once by means of the eye-glass. This interposed lens is called the *field-lens,* and that portion of the image which can be seen at once with the eye-glass is called the *field of view* of the microscope. [EYE-GLASS; FIELD; MICROSCOPE.]

FIELD-MARSHAL, a military dignity conferred on generals and commanders of armies for distinguished services, and also as a compliment to persons of high personal rank, as princes of the blood royal.

It has been supposed that the term marshal is derived from *Martis Seneschallus,* but it is more probable that it came from the Saxon words *mar,* or *marach,* a horse, and *scalck,* a servant; and it appears to have designated the person who had the care of a certain number of horses in the royal stables. In the Teutonic laws such a person is called *maris calcus,* and the fine for his murder is particularly specified.

The earl-marshal of England had originally the chief command of the army; and history records the names of two noblemen, De Montmorency and Fitzosborne, on whom the title was conferred by William the Conqueror.

The office was by Henry VIII. made hereditary in the family of the duke of Norfolk; but it is probable that it had before that time ceased to be connected with the military service; for from the 'Anecdotes of the Howard Family,' we learn that while another person held the post of earl-marshal, Sir Robert Willoughby Lord Brooke was appointed by Henry VII. to be marshal of the army.

The title of Maréchal de France appears to have become a military dignity in that country in the time of Philip Augustus; and, according to Père Daniel, the first person who held it was Henry Clement, the commander of the French army at the conquest of Anjou, in 1204. Originally there was but one Maréchal de France, but, in 1270, when the king, Saint Louis, went on his expedition to Africa, a second was appointed. Francis I. added a third; and the number has since been greatly increased.

The maréchaux de camp, in the old French service, were charged with the duty of arranging the encampment and providing subsistence for the troops; and in action they had the command of the wings, or of the reserve of an army, under the general-in-chief. From the title borne by this class of general officers is derived that of feld-marschall in the German armies; and from the latter title has arisen that which corresponds to it in the British service.

The number of field-marshals in the British army is at present four.

FIELD OF VIEW. [TELESCOPE.]

FI'ERI FA'CIAS, a judicial writ of execution issued on a judgment obtained in a personal action in the queen's courts. It is directed against the goods and chattels of the defendant, and is called a writ of *fieri facias,* from the words in it whereby the sheriff is commanded "quod fieri facias de bonis," &c., that he cause to be made of the goods and chattels of the defendant the debt or sum required. [EXECUTION.] It lies against privileged persons, as peers, &c., as well as other persons, and also against executors and administrators, so far as regards the goods of the deceased.

This writ, like all other writs of execution, being founded upon the judgment, must strictly conform to, and be warranted by, the terms of the judgment, or it will be void. By virtue of this writ, the sheriff may sell the goods and chattels of the defendant till he has raised enough to satisfy the judgment and costs, as well of the suit as of the execution; and also to satisfy any rent due to the landlord of the premises where the goods may be at the time of the taking, not exceeding one year's rent in the whole. If the judgment is not satisfied by the sale of the goods of the defendant, the plaintiff may have a capias ad satisfaciendum for the residue. [CAPIAS.]

The sheriff is not justified in breaking open any outer doors to execute this writ, but having peaceably obtained entrance, he may break open any inner door belonging to the defendant in order to obtain possession of the goods. The clothes which the defendant actually has on or in wearing cannot be taken, and royal palaces are privileged against the sheriff's intrusion for the purpose of levying upon the goods of a resident therein.

Formerly it was necessary that writs of execution should bear teste or date, and be returnable in term time; but now, by stat. 3 & 4 William IV., c. 67, they may be tested, that is, dated on the day when issued, whether in term time or vacation, and may be made returnable immediately after the execution thereof.

If a fieri facias is issued against a clergyman, and the sheriff returns that he has no goods upon which the judgment can be levied, but that the defendant is a beneficed clerk not having any lay fee, the plaintiff may sue out a "fieri facias de bonis ecclesiasticis," which is directed to the bishop of the diocese, or to the archbishop during the vacancy of the bishop's see, commanding him to make of the ecclesiastical goods and chattels of the defendant within his diocese the sum therein mentioned. It is tested and made returnable exactly in the same manner as a common fieri facias, and is executed by means of a sequestration issued by the registrar of the diocese. [SEQUESTRATION.] ('Bl. Com.' v. iii. Dr. Kerr's Edition; Archbold, Q. B. Pract. vol. ii.)

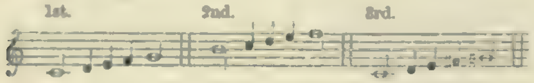
FIFE, a very small flute with never more than one key, and seldom that, giving acute piercing sounds, and used, together with the side drum, for military purposes, in marching, &c. It is an octave higher than the flute, and in compass comprises two octaves. Fifes are of three sizes, named by the letters A, B, and C. The first is the lowest; the last, which is that in common use, is the highest.

FIFTEENTH, in Music, is the interval of the double octave.

The *fifteenth stop* in organs is a range of metallic pipes, tuned two octaves higher than the diapasons.

FIFTH, an interval in music, and the most perfect of concords, the octave excepted. Its ratio is 3 : 2. [CONCORD; HARMONY.]

There are three kinds of Fifths; the *Perfect Fifth*, the *Flat* or *Diminished Fifth* (called also the *Imperfect Fifth*), and the *Extreme Sharp* or *Superfluous Fifth*. The first (C, G) is composed of three whole tones and a semitone; the second (B, F) of two whole tones and two semitones; the third (C, G ♯) of four whole tones. Ex. :—



FIFTH MONARCHY MEN, a sect of religionists, whose distinguishing tenet was a belief in the coming of a fifth universal monarchy, of which Jesus Christ was to be the head, while the saints, under his personal sovereignty, should possess the earth. They appeared in England towards the close of the Protectorate; and in 1660, a few months after the Restoration, they broke out into a serious tumult in London under their leader Venner, in which many of them lost their lives, some being killed by the military, and others afterwards executed. Several Fifth Monarchy Men also suffered death in 1662, on a charge (most probably unfounded) of having conspired to kill the king and the Duke of York, to seize the Tower, &c. They are the same who were sometimes called Millennarians, their notion being that the reign of Christ upon earth was to last for a thousand years. They seem, also, from the extravagance and violence of conduct into which they occasionally broke out, to have been confounded in the popular imagination with the old Anabaptists of Münster. [ANABAPTISTS.]

FIG, the *Ficus carica* of botanists, is a small tree, with rough, lobed, deciduous leaves, naturally inhabiting the temperate parts of Asia, and now commonly cultivated in Europe for the sake of its fruit.

In the fertile islands of the Mediterranean, in Spain, Italy, and Greece, and even so far north as the south of France, the fruit is so well ripened as to form a valuable article of exportation in a dried state. A thousand tons are annually imported into Great Britain alone. The fruit is grown with some success even in the southern and milder parts of England, but it is seldom found in the northern parts or in Scotland, except under glass. It is only as an object of cultivation in this country that we have to consider it in this place.

The nomenclature of figs is in a greater state of confusion than that of most other fruits, and the descriptions of them generally so imperfect that the same kind is grown in different parts of the country under many different names; an account of their synonyms, as far as they have been determined, will be found in the Horticultural Society's Fruit Catalogue, ed. 2.

The following is a list of the best sorts :—

Black Provence.
Large Blue.
Brunswick.
Blue Burgundy.
Early White.
Large white Genoa.
Hamburg Brown.
Black Ischia.
Brown Ischia.
Green Ischia.
White Ischia.
Yellow Ischia.
Lee's Perpetual.
White Malta.
Large Black Naples.
White Naples.
Small Green.
Brown Turkey.

The best sorts for forcing are :—

The Ashridge Forcing.
Figue Blanche.
Early Forcing.
Marseilles.
Nerii. (This excellent sort will not bear a high temperature.)
Pregussata.

The following kinds are recommended as a selection for a small garden, in the southern and midland counties of England :—

Black Ischia.
Brown Turkey.
Brunswick.
White Malta.
Large white Genoa.
Marseilles.
Small early White.

The following sorts have been recommended for a succession from August to October in the south of England :—

Brown Ischia . .	ripens in the middle of August.
Large white Genoa . .	„ end of August.
Green Ischia . .	„ beginning of Sept.
Murrey, or Brown Naples	„ middle of Sept.
Ford's Seedling . .	„ end of Sept.
Black Provence . .	„ beginning of Oct.
Yellow Ischia . . .	„ middle of Oct.
Gentile	„ end of Oct.

The most approved methods of propagating fig trees are either by layers or cuttings, and the former method is generally preferred, because the plants at the end of the season are stronger and more fit to be planted out where they are intended to grow. Trees raised from layers generally come into bearing the second year. Grafting succeeds upon these trees as well as upon any other, but it is almost unnecessary and seldom practised. Before the trees are planted the ground should be well drained, and made from two feet and a half to three feet deep, with a mixture of good friable loam and decayed dung. Miller remarks, that "fig-trees bear the greatest quantity of well-flavoured fruit when growing upon chalky land where there has been a foot or more of a gentle loamy soil on the top."

It was generally believed until a few years back that pruning was injurious to the fig, but experience shows this opinion to be unfounded, and that it is as tractable in this respect as any other tree.

The object to be always kept in view is to have constantly a supply of fruit-bearing shoots, and for this purpose the old wood should be gradually cut away, and the young introduced to fill the space thus created. Since the climate of this country will not admit of two crops in one year being brought to maturity, as in other countries more favourable to its growth, the fruit formed after midsummer should be removed, in order to strengthen the tree and render it more productive the following season.

Several modes of training are practised and recommended: some gardeners recommend the fan system, others the horizontal; but this must depend entirely upon the growth of the tree: if it be luxuriant, the latter may be practised; if not, the former will answer better; as the more perpendicular a tree is trained the stronger it grows, and a contrary effect is produced by horizontal training. Mr. Knight recommends the branches to be trained in a downward direction as well as horizontally, and says, "The young wood ceases to elongate very early in the season, and thence acquires perfect maturity, and by being trained close to the wall it is not so liable to be injured by frost."

In many parts of the continent where the winter is very cold, but where the summer heat is sufficient to ripen the fig, as a standard, the trees are planted in rows and bent down near the ground in winter, and then covered with leaves, which protect them from very severe frosts. Wall trees are unnailed and bent down on each side to within a few feet of the ground, and then protected in the same way as standards.

In this country the common practice is to stick yews, spruce-fir branches, or fern leaves amongst the branches of the fig upon the wall. Where anything can be used for protection which can conveniently be removed in fine mild weather, it will be found of greater utility than having the branches covered up from the commencement of winter until the end of spring.

When the trees are planted in the border of a hot-house for the purpose of being forced, they are commonly trained to trellises; and the treatment is precisely the same as that recommended for open walls. After the fruiting season the border must be kept perfectly dry, in order that the trees may enjoy a season of rest; but a plentiful supply of water is given when they are in a state of growth.

Those who have not a house which can be appropriated entirely to the forcing of figs may nevertheless obtain good crops by planting the trees in pots and forcing them in a cherry-house, peach-house, or vinery. The time for beginning to force is from December to February, according as the fruit is wanted; and the temperature should be gradually increased from 50° to 65° or 70° Fahr. Some also approve of a bottom heat, and recommend the pots to be plunged in a bed of leaves or tan.

The fig-tree is very apt to throw off its fruit before it ripens, and various methods have been suggested to prevent this. In the Levant, to insure a crop, a process termed caprification is resorted to, which consists in placing among the cultivated figs branches of the wild fig, in which a kind of Cynips abounds. This insect, issuing from the wild fruit, enters the others, brushing about the pollen in the inside, and so fertilising the fruit. Or those figs that drop prematurely and are chiefly filled with male flowers are preserved and introduced among the green growing figs with a view to their pollen being carried by insects to the flowers where they are wanted. To these processes the name of caprification has been given; but although sanctioned by a practice, the date of which is lost in antiquity, it has been conclusively proved by Professor Gasparrini that caprification produces no useful effect whatever upon the fig crop, and should be discontinued. (See 'Journal of the Horticultural Society,' vol. iii., in which the subject is very fully discussed.)

FIGURATE NUMBERS. [NUMBERS, APPELLATIONS OF.]

FIGURE (Geometry), a finite space, which has a boundary in every direction. The figure of a space is the notion we receive from observing its boundary.

FIGURE OF THE EARTH. [GEODESY.]

FIGURED BASE, in Music, is a line, or staff, written in the base clef, over the notes of which are placed figures representing certain chords. This is commonly called the *thorough-base.* [THOROUGH-BASE.]

The *figured base* is fallen into disuse, though we are of opinion that it might still be beneficially employed in scores. But in a piano-forte or organ part, when the harmony or accompaniment is given fully in the treble staff, figures are not only superfluous, but perplexing and incorrect.

FILBERT, the fruit of a variety of the hazel-nut, or *Corylus Avellana.* [CORYLUS.] The term was originally applied to those kinds of nuts which have very long husks, but owing to the number of varieties that have of late years been obtained, this distinction, which was never scientific, appears to be nearly disregarded, and nut and filbert are almost synonymous terms, excepting that the wild uncultivated fruit, and those varieties which most nearly approach it, are never called filberts.

The best sorts are the following:—

Frizzled filbert, excellent bearer.
Red filbert, } bad bearers.
White filbert, }
Cob-nut (Pearson's Prolific, 'Hort. Soc. Cat.'), a very prolific kind.
Bond-nut.
Cosford.
Large square Downton.
Northamptonshire, prolific.

According to the most skilful cultivators, the soil on which the filbert succeeds best should consist of "a hazel loam of some depth, upon a dry subsoil;" but as this is not always found convenient, it should be remarked that it is not essential to the growth of the filbert, and some even recommend a dry poorish soil. The ground should be frequently dressed (at least once in two years), and a small quantity of manure given; woollen-rags are often used for this purpose with the greatest success, but manure of any kind will be found beneficial.

Filberts are most successfully propagated by layers or suckers. The layering should be performed in the earlier part of the season, in order that the plants may be well rooted, and ready to plant either in a nursery, or where they are intended to remain, in the autumn. When they are raised from suckers, these are generally taken from the parent plant in the end of the season, and subjected to the same treatment as layers. If it be desirable that the trees should be dwarf, layering and grafting are recommended; but if strong plants are wanted, they are raised from suckers: it is also said they fruit sooner by the last method.

The method of pruning depends in a great measure upon the object the cultivator has in view: if dwarf trees are wanted, the layer or sucker is shortened to about one foot and a half or two feet; if what are termed riders be desirable, then the stem is cut much higher; but if the shoot is weak it is better to cut it near the ground, and leave it the proper height at the next year's pruning. Afterwards, when any sucker makes its appearance at the bottom of the stem, it should be carefully removed, and not allowed to draw the nourishment from the parent plant.

In the formation of the head, the chief thing to be observed is to form it regularly, cutting away all strong superfluous shoots, keeping it thin and open in the centre, and thus allowing the free passage of light and air. "There will be produced from the two and three years' branches, annually, short twigs of six or nine inches in length, which generally bear a great many nuts the following year; these should be thinned out, but not shortened, leaving them in tolerable quantity wherever they are produced, cutting them clean out the following winter, and leaving others in the same manner as those had been left the previous season." ('Lindley's Guide,' &c.)

About Maidstone, and other parts of Kent, the management of the filbert is better understood than in any other part of this country; and as the soil and other circumstances seem to suit its growth, immense quantities are grown for the London market. "That part of Kent where the filbert is chiefly cultivated is a loam upon a dry sandy rock. The Rev. W. Williamson advises every one to plant them where they are to remain, whether they are intended for a garden or a larger plantation; and after being suffered to grow without restraint for three or four years, to cut them down within a few inches of the ground. From the remaining part, if the trees are well rooted in the soil, five or six strong shoots will be produced. In the second year after cutting down, these shoots are shortened; generally one-third is taken off, and that they may appear regular, a small hoop is placed within the branches, to which the shoots are fastened at equal distances; by this practice, two considerable advantages are gained, the trees grow more regular, and the middle of each is kept hollow so as to admit the influence of the sun and air: but this in a large plantation would be almost impossible, nor indeed is it necessary, though in private gardens, where regularity and neatness are almost essential, it ought to be practised. In the third year a shoot will spring from each bud; these are suffered to grow till the following autumn, or fourth year, when they are cut off nearly close to the original stem, and the leading shoot of the last year shortened two-thirds. In the fifth year several small shoots will arise from the base of the side-branches which were cut off the preceding year; these are produced from small buds, and would not have been emitted, had not the branches on which they are situated been shortened, the whole nourishment being carried to the upper part of the branch.

"It is from these shoots that fruit is to be expected. These productive shoots will in a few years become very numerous, and many of them must be taken off, particularly the strongest, in order to encourage the production of the smaller ones; for those of the former year become so exhausted, that they generally decay; but whether decayed or not, they are always cut out by the pruner, and a fresh supply must therefore be provided to produce the fruit in the succeeding year. The leading shoot is every year shortened two-thirds, or more, should the tree be weak; and the whole height of the branches is not allowed to exceed six feet. Every shoot that is left to produce fruit should also be tipped, which prevents the tree being exhausted by making wood at the end of the branch. It frequently happens that a strong shoot springs from the root; and should any of the first year's or leading branches be decayed, or become unproductive of bearing wood, it will be advisable to cut that entirely away, and suffer the new shoot to supply its place, which afterwards is to be treated in the same way as is recommended for the others." ('Hort. Trans.' vol. iv.)

Such, according to Mr. Williamson, is the method of cultivating the filbert in the far-famed grounds of Kent, by which thirty hundred-weight per acre has been grown on particular lands; at the same time he acknowledges that failures are by no means unfrequent, but he attributes this to the excessive productiveness of successful years.

The filbert is a monœcious plant, having its male organs in one flower and its female in another; and one modern writer, suspecting a want of male blossoms to be the cause of failure in particular seasons, suspended a quantity of the catkins of the common hazel over the female blossoms of some of his filberts, the result of which was a greater quantity of fruit than his trees had borne for many years. He then tried some *with*, and others *without*, the male flowers, when the former bore fruit, and the latter proved abortive, as he had anticipated. He therefore recommends unpruned hazels to be planted among the cultivated filberts, in order that impregnation may be effected.

Great quantities of filberts are rendered useless by being attacked by the *nut-weevil* (*Balaninus nucum*), which perforates the nut in its young state, and deposits its egg: in a few days the maggot is hatched, and then feeds upon the kernel. Some recommend the trees to be shaken in June or July, as this is the time when the insect makes its appearance, but no remedy is known which can be said to be effectual.

In order to preserve filberts in a fresh and plump state, it is only necessary to prevent their parting with their moisture by evaporation. Burying them in heaps in the earth, putting them in earthen jars in a wine-cellar with a small quantity of salt dusted over them, covering them with dry sand, are all good plans, and many others equally efficient will suggest themselves.

FILE MANUFACTURE. Files are steel tools having flat or curved surfaces so notched or serrated as to produce a series of fine teeth or cutting edges. They are indispensable for the working of most metallic and many other hard substances; and without their aid few articles of machinery could be produced. The use of the file must have preceded every step in the progress of finishing articles composed of iron and steel, in all cases where any intricacy of shape precluded the operation of grinding. In the first book of Samuel (chap. xiii. v. 21), the file is mentioned as the means of sharpening the mattocks, coulters, and other edged instruments of the Israelites; and it may be mentioned as a further proof of the antiquity of this tool, that in Homer's 'Odyssey,' Vulcan is represented as using the hammer and file in fabricating the net in which he entangled Mars and Venus.

Files always are, or should be, made of steel of superior quality; as there are few instruments in which a defect in the metal is so completely destructive of utility. An axe, saw, or almost any other cutting instrument, though of inferior metal, may be made to do its duty by repeated whetting; but for a bad file there is no remedy,—no process of restoration. If too soft, the teeth wear down quickly; if too hard, they chip off. Steel for making files, being required to be of unusual hardness, is more highly converted than for other purposes, and is sometimes said to be *double converted.* The very large files called smiths' rubbers are generally forged immediately from the converted bars, which are, for convenience, made square while in the state of iron. Smaller files are forged from bars or rods which are wrought as nearly as may be to the required form and size by the action of tilt-hammers, either from blistered bars or from ingots of cast steel. These bars are cut into pieces suitable for making one file each, which are heated in a forge fire, and then wrought to the required shape on an anvil by two men : one of whom superintends the work, and is responsible for the goodness of the file, while the other acts as general assistant. Files being of many different shapes and sizes, as square, triangular, flat, round, and half-round in their cross section, and parallel or tapering more or less towards the end, and ranging from the minute watchmaker's files of an inch or two in length, to the ponderous rubber of two or three feet, there are of course many varieties in the forging process. The square and flat files are generally shaped by the hammer only ; but for those of a triangular or half-round section grooved bosses or dies of the required shape are attached to the anvil. Round files are made by means of the instrument known to smiths as a *swage*, which may be compared to a pair of such dies, one of which is inverted upon the other to receive the blows of the hammer. The projecting tang by which the file is to be inserted in a wooden handle is formed at this time, and the manufacturer's mark is impressed with a steel punch.

The next operation is that of softening or annealing, to render the steel capable of being cut with the toothing instruments. The ordinary mode of performing this operation is to pile the steel blanks loosely upon the bottom of a brick oven, and heat them with a fire kindled beneath and around them, the heat being regulated by dampers. When the fire has been maintained sufficiently long, the pile is smothered with ashes, every aperture by which air could enter the oven is carefully closed, and the whole is left to cool gradually. The access of air during the heating tends to the oxidation of the steel, and is consequently injurious : and on this account a more careful method of annealing is sometimes adopted, by means of a closely-covered box filled with sand, into the midst of which the blanks are plunged.

After annealing, the surface of the metal must be rendered very smooth and even before cutting the teeth. This may be done either by *stripping*, or filing, first across, and afterwards along the surface ; or by grinding upon very large grindstones. The stripping process, which is tedious and laborious, was formerly in common use, and is still practised by some filemakers, especially in Lancashire, where excellent files are manufactured ; but the other is now the most common method.

The cutting of the teeth is usually performed by workmen sitting astride upon a board or saddle-shaped seat, in front of a well-lighted bench, upon which is fixed a kind of small anvil. Laying the blank file across the anvil, the cutter secures it from moving by a strap which passes over each end and under his feet, like the stirrup of the shoemaker. He then takes in his left hand a very carefully ground chisel made of the best steel, and in his right a peculiarly shaped hammer, the handle of which is fixed at such an angle that the operator can, while making a blow, pull the hammer rather towards him. If the file be flat, or have one or more flat surfaces, the operator places the steel chisel upon it at a particular angle, and with one blow of the hammer cuts an indentation or furrow, completely across its face from side to side, but most commonly in an oblique direction ; the metal displaced by this operation is not taken away, but is thrown up in the form of a prominent angular ridge, with a sharp cutting edge, on one side of the furrow. He then moves the chisel a little, and by a second stroke cuts another precisely similar furrow parallel to, and at a very short distance from, the first ; and thus proceeds, stroke by stroke, until the whole surface is furrowed, beginning at the point and ending at the tang-end. In the course of cutting, the file is gradually moved from the operator by relaxing the pressure of the strap from time to time. In this state, the file is said to be *single-cut*, or *single-float ;* and files so cut are used for brass and the softer metals, which are liable to clog a file of any other kind. For working iron and some other materials, *double-cut*, or *cross-cut*, files are used ; in which the first row or series of cuts is crossed at an oblique angle by a second ; the effect of which is to convert the surface into a collection of very small angular teeth, admirably adapted for the abrasion of hard substances. In making cross-cut files, a fine file is gently passed over the first series of cuts or teeth to reduce the prominences to an even surface before the second set is cut. Files for wood are usually cut with a triangular pointed punch or chisel, instead of one with a flat edge ; such files, as well as some of the deepest and coarsest cross-cuts, are called *rasps*. If the file be round or half-round, or have any curved surface, it is still cut with the same kind of tool ; but as a straight-edged cutting tool can only make a short indentation upon a convex surface, it is necessary to go round the file by degrees, making several rows or ranges of minute cuts contiguous to one another.

In addition to variations in the form and arrangement of the teeth of files, their size varies extremely. The largest and coarsest smiths' files are called rubbers ; and others, arranged in order of fineness, are technically known as rough, bastard, second-cut, smooth, and dead-smooth files, the latter producing so fine a surface when applied to metal that the subsequent application of a burnisher is sufficient to polish it.

In the art of file-cutting there are many points worthy of remark. The angle at which the cuts are made depends greatly on the purpose to which the file is to be applied, and is made an especial object of the cutter's attention. The cut, too, is not a mere indentation, made without reference to form ; it is a triangular groove of particular shape, the production of which requires a most discriminating tact in the management both of the hammer and of the cutting-tool. Then, again, the strict parallelism of the several cuts can only be brought about by practised accuracy of hand and eye ; since there is no guide, gauge, or other contrivance for regulating the distance. In a round file, too, the several rows or cuts are brought side by side in such an exact manner that it is difficult to conceive them to be formed singly and by hand. It is possible, in a half-round file 10 inches long, to make 20,000 chisel-cuts, each produced by a distinct blow from a hammer ; and files of that length are actually made *single-cut*, with 10,000 such indentations.

The final process in the manufacture of files is the hardening of the steel, a process in which different manufacturers vary in practice. There are differences, too, depending on the degree of hardness required. In the ordinary process of hardening steel files three things must be particularly observed : first, to cover the surface of the file with some composition which, acting as a protecting varnish to it, may guard it from oxidation and scaling when exposed to the action of the fire, that the sharpness of the teeth may not be impaired, nor the surface rendered rough, which would cause it to clog when in use ; secondly, to heat it very uniformly throughout to a red heat ; and, thirdly, to cool it suddenly, by immersion in the freshest and coldest water, in such a manner as to impart the greatest degree of hardness, and to avoid the tendency to warping, which in long thin files is a difficult matter. A mixture very commonly used for the first-mentioned purpose consists of the grounds of malt liquor, or the cheapest kind of flour, yeast, and common salt. The use of the grounds is chiefly to enable the files to retain a greater quantity of salt, which fuses, and forms a protecting varnish when in the fire. The heating is usually effected in an open fire of clean coke, the file, if small, being held by the tang end in a pair of tongs, and frequently withdrawn, to see that no part becomes over-heated. The proper temperature is indicated by a cherry-red colour. A kind of oven is sometimes used for large files, to facilitate the uniform application of heat, the oven being formed of fire-bricks, open at one end to receive the files and fuel, and the fire being urged by bellows. Some file-makers put sulphuric acid or other substances into the quenching-water, with a view to procuring the greatest possible hardness. All files should be immersed quickly ; those of a flat, square, triangular, or round form, being plunged perpendicularly into the water ; while the half-round, though kept perpendicular, should be moved a little horizontally in the direction of the round side, to prevent its becoming crooked. With every precaution the files are liable to take some degree of warp or curvature in this process, to remove which they are withdrawn from the water before they become quite cold and straightened. Owing to their hardness, files are unavoidably brittle, and they are especially liable to break by the tang, owing to their reduced substance ; to remedy which, some makers temper the tang end by dipping it in a bath of melted lead. During the war of the French revolution, the supply of English files being impeded, the French file-makers were excited to great efforts to supply the deficiency ; and these efforts are said to have resulted in the production of files of intense hardness, by dipping them into a composition of mutton suet, hog's lard, and arsenic.

After hardening, the files are scoured with a brush dipped in water mixed with a little sand or coke-dust ; then thoroughly washed to remove any saline particles which might tend to rust the file ; next dipped in water in which quick-lime has been dissolved, in order to neutralise the effect of any which may yet remain ; and finally dried before the fire, brushed over with oil or a mixture of olive-oil and turpentine, and wrapped up in oiled brown paper for sale. Before packing, files are sometimes tested by striking them gently on a piece of hard steel, and also rubbing them gently from end to end.

When files, otherwise of good quality, are reduced to a useless state by wear, they are sometimes re-cut, the old teeth being completely removed by grinding. Re-cut files are, of course, somewhat thinner than when first made, but in all other respects they may be equally good, if the process is properly conducted. Owing to the superior quality of the steel, worn-out files bear a comparatively high value as old metal, and many are bought up for the purpose of converting them into screw-drivers and gun-barrels.

Several highly ingenious machines have been contrived for superseding the tedious operation of file-cutting by hand ; but, suited as the process may appear to be for the use of machinery, it has been found to present such great difficulties that few file-cutting engines have been brought successfully or extensively into operation. One very serious difficulty arises from the circumstance that if one part of the file be either a little softer than the adjacent parts, or narrower, so as to present less resistance to the blow of the hammer, a machine would, owing to the perfect uniformity of its stroke, make a deeper cut there than elsewhere ; whereas a workman who has been employed in the trade from a boy can feel instantly when he arrives at any variation in the quality or condition of the steel, and at once adapts the weight of his blow to it. The application of machinery to the toothing of extremely fine-faced files seems conceivable however, because in such the *set* or direction of the teeth is a matter of much less importance than perfect equality of surface. The double dead-cut files of the

French exhibit such a beautiful uniformity of delineation when examined with a magnifier, that no doubt seems to be entertained by many persons conversant with the art of their being cut by machinery of some sort. But although the French are so successful in the production of this exquisitely delicate cutting, they are not equally so in the execution of the rougher sorts; and, consequently, English files are in high reputation in Paris, whither large quantities are regularly transmitted. As an example of minute but useless work, we may adduce the Danish file sent to the Great Exhibition in 1851. It was four-square, and weighed 10 lbs.; the file-cuts on the surface represented the royal arms, and views of several public buildings in Copenhagen. It was hollow, and contained a nest of ten files, one within another, the innermost being little more than an inch in length. Still more pretentious was a file made by Hiram Younge, a file-cutter in the employ of Messrs. Carr of Sheffield; it was 54 inches in length, and was covered all over with landscapes, emblems, symbols, inscriptions, foliage, and other devices, all produced by chisel-cuts of different lengths and depths.

A brief notice of three among the many machines invented within the last few years will illustrate the modes in which the cutting-action is brought about, and will also show that there are really machine-cut files now made in England. In 1856, a file-cutting machine, invented by Mr. Ross, was adopted in Messrs. Hetherington's works at Glasgow; and by the spring of the next year, five others had been added. The chief difficulty hitherto has been in the attainment of a proper modification of blow, so as to suit various qualities of steel, widths of file, and depths of cutting; and also to accommodate the blow to any irregularities of surface. These difficulties Mr. Ross has sought to remove, by an ingenious but very complex arrangement of mechanism —calculated to produce files of a medium degree of size and fineness. In Messrs. Preston and Macgregor's machine, patented in 1858, there is a shaft turned by a strap in the usual way; conical cams, fixed on the shaft, raise and lower a hammer-head and spindle; there are fixed guides on the anvil block; the upper swage is fixed at the lower end of the spindle, and the lower swage between the guides; and thus the blows of the hammer are brought down vertically. The lift of the hammer is varied by varying the distance between the cams on the shaft. There is a chisel-holder with a ball-joint, and a spring for retaining the holder in its place. There is a compensating movement for regulating the force of the blow. The file-blank is placed in a recess in the anvil. Messrs. Greenwood and Batley set up at Leeds, in 1859, a file-cutting machine of French invention. The file, in this arrangement, is placed in a self-adjusting bed, capable of turning in any direction; the chisel is fixed in a vertical slide, put in motion by a spring and cam and gives about a thousand blows in a minute. It is said to do about as much work as ten skilful file-cutters. This form of machine is also in operation in France and Belgium.

Files are among the articles which exemplify the importance of trade-marks. A mark was granted many years ago by the Sheffield corporation to Daniel Brammall, to be stamped on his files; and so important was this in a commercial point of view, that on one occasion Brammall obtained 2000*l*. damages against a rival manufacturer, for an infringement of the mark. This matter was adverted to by one of the jurors of the Paris Exhibition in 1855, in connection with the file-manufacture:—"The fundamental obstacle to the growth of this branch of industry results from the custom adopted by almost all manufacturers of placing false marks on their produce. This deplorable custom is due in part to the desire that unconscientious manufacturers, convinced of their real inferiority, have to turn to their own profit the resources of the best foreign manufacturers, acquired by a long career of honesty and talent; it is encouraged by the retail dealers, who wish to keep manufacturers dependent on them, and to hinder the consumer from knowing the real marks of steel goods. Manufacturers, short of capital, submit in this matter to the terms dictated to them by the dealers, renounce their individuality, and stamp upon their goods such marks as the buyer chooses to order, and even to substitute the name of the retail dealer for their own. The history of the English steel trade proves that a skilful manufacturer, who consecrates his life to found the reputation of the trade-mark he has chosen, can leave in the sole possession of that mark a large fortune to his descendants. The government would, therefore, render skilful and conscientious manufacturers (the only ones that ought to be encouraged) an immense service in imposing upon each producer the obligation to place his own mark upon his manufactures." It is probable that this mention of government interference was due to a Frenchman, with whom such a mode of settling trade difficulties is familiar. In reference to the file-manufacture, the chief piracies occur in Germany, where English trade-marks are copied with unblushing effrontery.

FILE, is a line of soldiers one behind the other. The term is commonly used also to designate a front and rear rank man together; or as in the expression so many rank and file, when it means so many soldiers who are not officers or sergeants.

FILE MARCHING, is where a line of soldiers, either in single or double rank, facing to the right or left, march in that direction; each front and rear rank man then compose a file.

FILIATION, ORDER OF. [BASTARDY.]

FILLET, a flat rectangular moulding, of very frequent occurrence in architecture. It is used to terminate or divide other mouldings, as in the cavetto, which is surmounted with a fillet, and in the flutings of columns, which are divided by a fillet. The fillet is much used in entablatures. [COLUMN.]

FILTER; FILTRATION. Filters may be ranked as of four kinds: those employed in straining various chemical liquids; those used for filtering water in small quantities for household use; those used on a large scale by the water companies; and those used on shipboard for converting salt water into fresh.

1. *Chemical filters.* The smaller kinds are strainers used in chemical operations for rendering fluids transparent by separating the suspended impurities which make them turbid; or for separating and washing the precipitates resulting from chemical analysis. They are usually made of unsized or blotting paper; and they are used either spread out upon cloth stretched on a wooden frame, or folded and placed in funnels, and having consequently the form of an inverted cone. They are either single or double, according to the purposes to which they are to be applied. [CHEMICAL ANALYSIS.]

2. *Household filters.* Various forms of filter are employed for the purpose of filtering water, either for drinking or culinary purposes. These filters generally depend upon passing water through sand or small pebbles and charcoal. It is well known that the Thames water, though it contains but little saline matter in solution, is frequently turbid, owing to mechanical admixture of earthy matter; and these earthy matters, in the Thames and other kinds of river water, it is the purpose of filters to remove, so as to render the water, though not so agreeable as spring-water for drinking on account of its flatness, yet well adapted for other purposes.

A considerable portion of the river-water of Paris is filtered in large establishments where it is employed. The filters made use of are small boxes, many in number, lined with lead, open at top, and having at the bottom a layer of charcoal between two layers of sand. If the water is foul, the upper layer of sand requires to be renewed daily. At the Hôtel Dieu the boxes are hermetically sealed, and the water is forced through the filtering layers by artificial pressure.

A very simple water-filter may be made of a common garden-pot, or similar vessel, with a bottom pierced with holes. Fill the lower part with round pebbles, then place a layer of smaller pebbles, then coarse sand, and lastly a layer, three or four inches in depth, of well-made pounded charcoal. The water, in percolating through these various strata, loses nearly all its mechanical impurities. A still simpler filter may be formed of a layer of sponge pressed between two perforated plates.

Murray's Self-cleansing Domestic Tubular Filter is soldered to the end of the service-pipe. The enlarged part of the pipe contains a perforated tube with several folds of flannel and linen wrapped round it. The smaller tap communicates only with the outer casing, so that no water can reach it that has not passed through the filtering tube. The larger tap communicates with the interior of the tube; and by allowing it to run, the filter will cleanse itself. In Bird's Hydrostatic Syphon Water Purifier, the filtration is performed in two inverted cones containing filtering media, situated in the cylinder. When used, the instrument is immersed in the water to be filtered, and the pipe uncoiled so as to hang with its stop-cock below the bottom of the instrument. On drawing out the air from the pipe, it acts as a syphon, and a stream of pure water flows. Foster's Pressure Filter, recommended for use by the Sanitary Board of Liverpool, consists of a porous stone, hollow in the inside, and contained in a metal jacket. This apparatus, when screwed into the service-pipe, causes the water, forced through the stone by the pressure of the main, to lose all its pollutions, and come out pure and clear. There are two taps, one of which draws the filtered water from the interior of the stone globe; the other the unfiltered from the exterior; and the apparatus is so arranged that the drawing of the unfiltered water cleanses the stone and increases its powers of filtration.

Some of the filters recently made have for their object the maintenance of a uniform pressure of the fluid upon the filtering surface by a self-acting contrivance, which admits the fluid from a reservoir just as fast as it passes off through the filter. On a small scale this may be done by inverting a bottle, filled with the liquid to be filtered, with its open neck or mouth in the funnel or other vessel at the bottom of which the filtering materials are placed; so long as the fluid in the funnel is above the level of the mouth of the bottle, no fluid will flow from the bottle into the funnel, because no air can enter the bottle to take its place; but so soon as, by the process of filtration, the fluid in the funnel falls below the mouth of the bottle, air enters it, and consequently liquid flows out into the funnel until it rises high enough again to prevent the admission of air. In other cases, the admission of fluid to the filter is regulated by a ball-cock or valve connected with a float. In a few instances, hydrostatic or pneumatic pressure is employed to increase the rapidity of filtration, by closing the filtering cylinder, and forcing the fluid into it, either by a force-pump or by a pipe from an elevated cistern; by producing pressure by air or steam upon the surface of the fluid; or by occasioning a partial vacuum beneath the filter, in the vessel which receives the fluid after it has passed through it. When such pressure is applied, the water or other fluid is sometimes caused to *ascend* through the filtering materials, or to pass through them horizontally, or in any required direction. In some filters, the action is compounded of descent by gravity and ascent by hydrostatic pressure; by which arrangement the fluid may be compelled to pass through a great quantity of filtering material in a small space. In one form, the filtration is carried on without any exposure to the access of air; both the vessel into which the impure fluid is put, and that which receives it after filtration, being hermetically closed. These two vessels are connected together by a small air-pipe, through which the air displaced from the lower vessel by the dropping of the fluid into it ascends into the upper vessel to occupy the space which it has just vacated. The process therefore is conducted without the contact of any more air than the vessels contain at its commencement, and without the escape of any vapours from the fluid; so that the most volatile liquids may be filtered without loss, and the injurious effects which in other cases might arise from the free admission of air are avoided.

In Ransome's filter, patented in 1856, there is a cylindrical vessel, at the bottom of which is a layer of coarse grit; above the grit is a layer of fine sand; and above this a slab of Ransome's patent porous stone. In the middle of the porous slab is a hollow space containing a layer of charcoal. Above all these layers is a vessel for filtered water; and above and around this another for unfiltered. The impure water runs down to the bottom of the vessel, and then ascends through all the layers, leaving the impurities behind it. Filters of this kind are found to be more easily cleaned than those which act by descension. Ransome's patent stone has led to the production of a very small and simple filter, intended for troops, travellers, and emigrants. It consists of a small cylinder of porous stone, attached to a disc of wood; from which disc springs a short vulcanised india-rubber tube, with a mouth-piece. On placing the cylinder in unfiltered water, and drawing breath through the tube, water rises in a tolerable state of purity, and flows into the mouth.

3. *Filtering Beds.*—The processes for filtering water on a large scale, as now adopted by the chief water-works companies, will best be treated in the article WATER-WORKS.

4. *Freshening Sea-Water.*—This important process, becoming every year more appreciated and more extensively adopted, belongs rather to distillation than to filtering; but it was referred from DISTILLERY to this place, because many of the forms of apparatus employed comprise filtering as well as distilling arrangements. It may not at first sight appear evident how the saltness of sea-water can be removed by either of these processes. The explanation is found in the fact, that whenever water is converted into steam at an ordinary temperature, very few if any solid particles ascend with it. Salt, clay, sand, charcoal, alkalies, and oxides, are almost wholly left behind in the vessel in which the water is treated; the vapour which passes off consisting of aqueous particles and a little atmospheric air. If clear water, dirty water, or sea-water be placed in a common kettle on the fire, the steam that issues from the spout will be nearly alike in all three cases; it will be vapid and tasteless, but neither salt nor impure. The possibility of rendering sea-water drinkable is a question of very great importance to ship-owners, especially to the owners of emigrant and passenger ships, and to the royal navy; for, under present arrangements, a vast space and a vast number of tanks are necessary to contain fresh water enough for the wants of all the crew and passengers; and even if fresh when put on board, the water has a tendency to become foul by long keeping. The miseries suffered on ship-board by a deficiency of pure water are among the greatest to which passengers and crew are liable.

All the many forms of apparatus invented for freshening sea-water are contrived with a view to making the best use of the fuel employed; those which are most economical are most likely in the end to be adopted. Grant's apparatus, brought forward in 1849, is so contrived that the same fire employed for the cooking of the crew's provisions will distil sea-water contained in a vessel above it, at the rate of one gallon per man per day. The water becomes aerated, or mixed with sufficient atmospheric air to impart briskness to it, by agitation in the vessel. McBride's apparatus, patented in the same year, condenses the heated sea-water by a current of cold air, which gathers it into a condenser by means of a blowing or exhausting machine. Murdoch's apparatus comprises a pipe fitted in the top of the ship's cooking boiler, and another perforated pipe to admit air; an exhausting space sucks both the steam and the air down the pipe into a condenser beneath, thereby effecting simultaneously the distilling and the aerating. In Ericsson's apparatus, when the sea-water has been converted into vapour, the steam passes into and through a space between two concentric vessels; the inner vessel is kept cool by the flow of cold water through it, and the outer one by the evaporative action of the atmosphere on a wet cloth wrapper; and the steam being thus placed between two cool surfaces, becomes condensed into drinkable water. In Normandy and Fell's apparatus, the arrangement is somewhat peculiar. There is a cylinder surrounded by a steam-jacket. The cylinder is divided internally into four channels or compartments by partitions. Each of these compartments is turned up at one end, so as to allow the water to flow towards the other. The cylinder is connected at one end to a pipe with a condensing and aerating apparatus, contained within a closed tank; and at the other by a pipe with a box, into which the water to be purified is first introduced. A pipe brings steam from a boiler into the jacket, to heat the cylinder. The sea-water within the cylinder is made to flow through all the compartments, by means of the partitions; it gets heated as it goes, and throws off steam. This steam passes off through the pipe into the condenser, where it gets mixed with atmospheric air, and is finally condensed by coming in contact with the sides of the condenser. The steam which has been employed in heating the cylinder when condensed by cold, is drawn off by another pipe; although it is not pleasant to drink, through not being aerated, it is still good enough for washing. The residuum of the salt or impure water escapes by another pipe. Gravely's apparatus, patented in 1858, consists of two parts, a boiler and a condenser, the latter over the former. The bottom of the boiler is corrugated, to increase the heating surface, and there is a jacket to economise the heat. A pipe extends from an aperture in the top of the boiler to near the top of the condenser; a larger pipe is outside and concentric with this; and the space between them is an air-space.

Messrs. Gravely have recently paid much attention to their apparatus, to render available as much as possible of the heat which in ordinary ships is usually generated in the cook-room; and their success has been such as to lead to a large employment of the apparatus in merchant ships. Grant's apparatus, applied some years ago to H. M. S. Arrogant, Plumper, Reynard, Dauntless, Termagant, and Encounter, has recently, modified and improved by other contrivances, been provided for a large number of ships in the royal navy. When Sir Charles Napier was in the Baltic with his fleet, eleven ships distilled 4,700 tons of sea-water; and did this so well, that the crew preferred the water thus obtained to ordinary fresh water. In the Black Sea during the same war, the ship Wye distilled 10,000 gallons a day. Very recently (1859) Dr. Normandy, improving on an apparatus in which he was concerned some years earlier, has brought it to a more efficient state than any other for the Royal Navy; it is now being largely adopted by the Admiralty, and by the great steam mail companies.

FILTRATION. A process used in chemical operations to separate solid from liquid matter. [CHEMICAL ANALYSIS.]

FINA'LE (Ital. *Fi-ná-le*), the concerted piece of music by which the acts of an opera conclude: the last movement of a symphony, concerto, &c.

FINANCE. [TAX; TAXATION.]

FINE OF LANDS, one of the modes of conveying lands and hereditaments by matter of record. It was so called because it put an end not only to the actual suit of which it was the conclusion, but also to all other suits and controversies concerning the same matter. Divested of its technicalties, a fine may be described to be an amicable composition or agreement of a suit, either actual or fictitious, by leave of the king or his justices, whereby the lands in question become, or are acknowledged to be, the right of one of the parties.

The note of the fine was read four times openly in the Court of Common Pleas, or as it was called, proclaimed, once in the term in which it was made, and once in each of the three succeeding terms, during which all pleas ceased, and these proclamations were endorsed upon the record. A table of the fines levied in each county in every term was affixed in some open part of the Court of Common Pleas all the next term, and a copy of the same was given to the sheriff of every county, who at the next assizes fixed the same in some open place in the court, for the more public notoriety of the fine. (Bl. 'Com.' vol. ii. p. 351, Mr. Kerr's ed.)

Of the effect of a Fine.—A fine was a conveyance so effective that it bound not only those who were parties and privies to the fine, but all other persons whatsoever, unless they brought their action or made lawful entry within five years after proclamation made, except married women, infants, prisoners, persons beyond the seas, and such as were not of whole mind, who had five years allowed to them and their heirs after the death of their husbands, their attaining full age, recovering their liberty, returning into England, or being restored to their right mind. Persons also who had not a present, but a future interest only, as those in reversion or remainder, had five years allowed them to claim in from the time their right accrued by the stat. 4 Henry VII. c. 24.

In order to make a fine of any avail at all, it was necessary that the parties should have some interest or estate of freehold in the lands to be affected by it. (Bl. 'Com.' vol. ii. p. 358, Mr. Kerr's ed.) But it was not necessary that the freehold should be in either of the parties by right, and therefore when a fine was levied to strengthen a title, it was frequently considered necessary to make a feoffment, in order that the freehold might be in one of them by disseisin. [FEOFFMENT.] If neither of the parties had any interest at the time, although the fine had no proper operation, yet it might take effect as between them by way of estoppel. [ESTOPPEL.]

A fine was principally used as the mode of conveying the estates of married women, and renouncing their right to dower, as a means of barring estates tail, and remainders and reversions dependent upon other estates, and also for the purpose of strengthening defective titles.

By the 3 & 4 Will. IV. c. 74, fines are abolished, and provision is made for the conveyance of the interest of married women in land, with the concurrence of their husbands, and after being examined to ascertain if they are acting voluntarily, by a deed to be acknowledged in the Court of Common Pleas; and provision is also made for the barring of estates tail by a deed enrolled: but no provision is made for enabling parties whose titles are defective to strengthen them by any means analogous to a fine and nonclaim. (2 Bl. 'Com.'; Cruise, 'On Fines.'

This mode of conveyance, which was in use from the earliest periods of English history of which we possess any authentic judicial records, has been recently abolished by the stat. 3 & 4 Wm. IV. c. 74; yet the rules by which it was governed form a very considerable branch of real property law, and it is therefore desirable briefly to describe its nature and effect. Fines were of four kinds:—1. A fine "sur conusance de droit, come ceo qu'il ad de son done;" that is, upon acknowledgment of the right of the cognizee, as that which he (one of the parties to the fine) had of the gift of the cognizor (the other party to the fine). This was the best and surest kind of fine, for thereby the cognizor (the person in possession, also called the deforciant from keeping the cognizee out of possession), in order to make good his covenant with the cognizee (the plaintiff), of conveying to him the lands in question, and at the same time to avoid the formality of an actual feoffment and livery, acknowledged in court a former feoffment, or gift in possession, to have been made by him to the plaintiff. This fine is therefore said to have been a feoffment of record, the livery thus acknowledged in court being equivalent to an actual livery; so that this conveyance was rather a confession of a former conveyance than a conveyance then originally made. 2. A fine "sur conusance de droit tantum," or upon the acknowledgment of the right merely; and not with the circumstance of a preceding gift from the cognizor. This was commonly used to pass a reversionary interest; for of such there could be no feoffment with livery supposed, as the possession during the preceding, or, as it is technically called, particular estate, belonged to a third person. [FEOFFMENT.] This kind of fine was worded in this manner: "that the cognizor acknowledges the right to be in the cognizee, and grants for himself and his heirs that the reversion after the particular estate determines shall go to the cognizee." 3. A fine "sur concessit," which was where the cognizor, in order to make an end of disputes, though he acknowledged no precedent right, yet granted to the cognizee an estate usually for life, or for years, by way of supposed composition. And this might be done reserving a rent or the like, for it operated as a new grant. 4. A fine "sur done, grant, et render," which was a double fine, comprehended the fine "sur conusance de droit come ceo," &c., and the fine "sur concessit." This might be used to create particular limitations of estate, whereas the fine "sur conusance de droit come ceo," &c., conveyed nothing but an absolute estate of inheritance, or at least of freehold. In this last species of fine, the cognizee, after the right was acknowledged to be in him, granted back again, or rendered to the cognizor, or perhaps to a stranger, some other estate in the premises. But in general, the first species of fine, "sur conusance de droit come ceo," &c., was the most used, as it conveyed a clear and absolute freehold, and gave the cognizee a seisin in law, without any actual livery, and it was therefore called a fine executed, whereas the others were but executory.

Fines of all four kinds were thus levied, to use the technical term: First, the party to whom the land was to be conveyed commenced an action or suit at law against the party who was to convey, by suing out a writ or *præcipe*, called a writ of covenant. The action was founded upon the breach of a supposed agreement or covenant, that the one should convey the lands to the other. On this writ a fine, called a *primer fine*, amounting to about one-tenth of the annual value of the land, became due to the king. The suit being thus commenced, then followed,—Secondly, the "licentia concordandi," or leave to compromise the suit, upon which also another fine, called the king's silver, or sometimes the post fine, became due to the king, amounting to about three-twentieths of the annual value of the land. Thirdly, came the concord or agreement itself, which was required to be made either openly in the Court of Common Pleas or before the lord-chief-justice, or one of the judges of that court, or two or more commissioners in the county specially authorised; all of whom were bound by stat. 18 Ed. I. s. 4, to take care that the cognizors were of full age, sound memory, and out of prison. If a married woman was a cognizor she was privately examined by the parties before whom her acknowledgment was taken, whether she did it freely and willingly, or by compulsion of her husband. A fine was the only way in which a married woman could convey her freehold interest in lands.

By these several acts the essential parts of the fine were completed, and even if the cognizor died, still the fine might be carried on in all its remaining parts, of which the next was—Fourthly, the note of the fine, which was simply an abstract of the writ of covenant and the concord; naming the parties, the parcels of land, and the agreement, for the purpose of enrolment of record in the proper office. The Fifth and last part was the foot of the fine, which included the whole matter, reciting the parties, day, year, and place, and before whom it was acknowledged or levied. Of this indentures were made or engrossed at the chirographer's office, and delivered to the cognizor and the cognizee, usually beginning thus: "hæc est finalis concordia" ("this is the final agreement"), and then reciting the whole proceeding at length.

FINGER-BOARD, the whole range of keys, white and black, of a piano-forte or of an organ.

FINGERING, in music, is the art of so applying the fingers to a musical instrument, the piano-forte and organ especially, as to accomplish the objects in view in the easiest and most effective manner. A proper notice of the art of fingering, accompanied by the necessary examples, would require many pages; we shall therefore only remark in this place that, as a system, Clementi's is the best that we are acquainted with; though some few modern improvements have been made in its details.

FINIAL, a term used to designate the knob of foliage, or the floral ornament which crowns the apex of pinnacles, pediments, canopies, low spires, and occasionally gables, pointed dripstones, &c. in Gothic buildings. Formerly, pinnacles were frequently called finials, but the term is now limited to the top ornament. [GOTHIC ARCHITECTURE.]

FININGS. In brewing, and other manufacturing operations, a process of clarifying or clearing is required, for which some substance is employed under the name of *fining*. Some of these finings are made by the persons who are to use them; while others are purchased from the makers. Isinglass is made into finings by mixing it with beer or cyder, stirring until the isinglass is dissolved, straining through a sieve, and finally bringing it to a liquid state by mixing with the same kind of beverage as that which is to be fined. This is a fining much used by brewers. Distillers or rectifiers, in clarifying gin and cordials, use a fining composed of alum mixed either with carbonate of soda or salt of tartar and hot water.

It is a disputed point whether finings are really necessary in well-brewed malt liquors in good condition. Mr. Cooley and Dr. Ure decide this in the negative. The former observes: "Good liquors, either fermented or spirituous, need no artificial fining, as they always clarify themselves by repose. With those, however, which are out of condition, or of inferior quality, it is often necessary; as without such a proceeding they remain unsaleable. This is particularly the case with malt liquors." "Attempts to clarify it in the cask," says Ure, "seldom fail to do harm. The only thing that can be used with advantage for fining foul or muddy beer is isinglass. The disadvantages resulting from the artificial clarification of fermented liquors are, that the liquors do not afterwards stand well on draught; that much of the conservative astringent matter which they contain is precipitated with the finings; that their piquancy and flavour are more or less diminished; and that they are more than usually liable to become flat and vapid, whether in cask or in bottle. The larger the proportion of finings used, the more marked are their injurious effects, and the shorter the interval which elapses before the accession of the several symptoms referred to. We have seen the most disastrous consequences follow the injudicious use of finings, more especially in respect to those liquors in which a certain amount of piquancy, astringency, and briskness is an essential condition. In one instance which came under our notice, upwards of thirty barrels of 'underground,' a very strong old ale, was thus reduced in value to less than one-third of its original cost; and in another, a large bottled stock of the finest old Burton was found to be utterly unsaleable. In both cases, the spoiled liquor was got rid of by mixing it in, and selling it with, 3*d*. and 4*d*. ale."

FINITE (in Mathematics), having a boundary, used as opposed to INFINITE.

FIR, ECONOMICAL USES. In giving a brief notice of some of the remarkable and numerous uses of the fir-tree, we shall include at the same time the pine, which is so nearly allied to it as to have been placed by some botanists in the same genus.

The timber of the fir and pine is, perhaps, all things considered, more generally useful than that of any other tree. It is far excelled in strength and toughness by the timber of the oak, elm, beech, &c.; but it is more easily worked, and is durable enough for a large number of purposes. Some kinds are useful for the masts of ships; others for parts of the hull; others for flooring-boards. What Michaux says of the use of the white pine in North America will serve as well as anything else to denote the wide range of usefulness possessed by this timber: "The ornamental work of the outer door, the cornices of apartments, and the mouldings of fire-places, all of which in America are elegantly wrought, are of this wood. It receives gilding well, and is therefore selected for looking-glasses and picture-frames. Carvers employ it exclusively for the images that adorn the bows of vessels, for which they prefer the kind called the pumpkin pine. At Boston, and in other towns of the Northern States, the inside of mahogany furniture and of trunks, the bottoms of Windsor-chairs of an inferior quality, water-pails, a great part of the boxes used for packing goods, the shelves for shops, and an endless variety of other objects, are made of white pine. In the district of Maine it is employed for barrels to contain salted fish, especially the kind called the sapling pine, which is of a stronger consistence. For the magnificent wooden bridges over the Schuylkill at Philadelphia, and the Delaware at Trenton, and for those which unite Cambridge and Charlestown with Boston, of which the first is 1500, and the second is 3000 feet in length, the white pine has been chosen for its durability. It serves exclusively for the masts of the numerous vessels constructed in the northern and middle states; and for this purpose it would be difficult to replace it in North America." If Michaux had lived to the present day, he would not have failed to notice the vast use of pine and fir timber in railway construction. In the newly-cleared regions of America, and in many parts of Russia, corduroy roads, as they are called, are made of trunks of pine and fir, slightly dressed, and laid transversely to the length of the road.

Chips of some kinds of pine contain much resin or pitch, which render them useful as flambeaux in countries where candles and lamps are too expensive for the poorer cottagers. In one or other of the various kinds of pine and fir, all parts of the tree are made to render useful service. The fragments of wood yield fuel and charcoal; the ashes of the burnt roots, &c. furnish potash; the bark is useful in tanning; the buds and young shoots are made into spruce beer; the young shoots mixed with corn are food for cattle, sheep, and horses, in some countries; the inner bark is made into baskets; the long and slender rootlets furnish a kind of tough twine; the outer bark is used in Lapland and Russia for covering and lining huts, and as floats for fishing nets. The food of man is not without a supply from the fir and pine. The cones are sometimes used to flavour wine; the Laplanders make a coarse bread-flour from the inner bark; the kernels of some species are eaten as a substitute for hazel nuts, and are used in confectionary as a substitute for almonds; the kernels of one species yield much oil, useful both for food and for lamps; and the shells yield a rich dye.

Besides all the above useful substances, there are others yielded by these trees, due chiefly to the sap or juices. Common turpentine, Venice turpentine, Strasburgh turpentine, black resin, yellow resin, tar, common pitch, Burgundy pitch, lampblack—all are obtained, either from the living tree, or by the application of heat to the trunk and root when dead.

FIRE. [COMBUSTION; HEAT.]

FIRE (*Direct, Enfilade, Oblique, Plunging, Ricochet, Reverse, Slant*, or *Vertical*), are terms applied to the fire of a battery, according to its direction with respect to the object fired at.

Direct, when it is perpendicular to the face of the work or line of troops fired at.

Enfilade, when it is in the direction of the length of the face of a work or line of troops, or in the direction of the greatest length of a column or mass of troops. The battery will then be on, and ranged perpendicular to, the prolongation of such face of work or line of troops enfiladed.

Oblique, when it makes an angle with the front of the object fired at.

Plunging, when it is from a position higher than the object fired at.

Ricochet, when *enfilade* is with small charges. [RICOCHET.]

Reverse, when it strikes the interior slope of a parapet, or the rear of a line of troops, at an angle greater than 50°.

Slant, when it strikes the interior slope of a parapet, or rear of a line of troops, at an angle less than 30°.

Vertical, when the shot, having been fired at an angle of 45° or more, falls almost perpendicularly.

FIRE-ARMS. [ARMS; ARTILLERY.]

FIRE-BOTE. [COMMON, RIGHT OF; ESTOVERS.]

FIRE-DAMP. [METHYL, *hydride of*.]

FIRE-ENGINE, a term formerly applied to the steam-engine, but now confined to those machines which are employed to extinguish fires by throwing water from a jet upon the burning materials.

There were various modes of extinguishing fires previous to the invention of the modern fire-engine. A term employed by Juvenal and Pliny expressive of some implement used in extinguishing fires has given rise to some discussion. This term is Hama, which some commentators describe as a water-vessel; but Holstein contends that it was a very large hook or grapple fixed at the end of a long pole. Pliny the younger speaks also of pipes (siphones) being used to put out fires. Augustus appointed seven bands of firemen in Rome, each of which had the care of two divisions (regiones) of the city; each band had a captain (tribunus); and at the head of the whole body was the prefect of the watch (Præfectus Vigilum). With regard to such contrivances as might correctly come under the denomination of machines, it appears that they originated with Ctesibius, a distinguished Greek mechanician, who lived in Egypt in the reign of Ptolemy Philadelphus. Hero, a pupil of Ctesibius, describes a sort of forcing-pump with two cylinders, employed for the purpose of extinguishing fire. Apollodorus, architect to the Emperor Trajan, has left a description of a machine consisting of leathern bottles with pipes attached to them: when any bottle was squeezed, a jet of water flowed through the pipe, and was thus used to extinguish fires. Beckmann has found, in the accounts of many of the German towns, entries for the cost of machines, the existence of which would be very problematical without that evidence: thus, in the building accounts of the city of Augsburg for 1518, fire-engines are mentioned under the name of "instruments of fire," or "water-syringes."

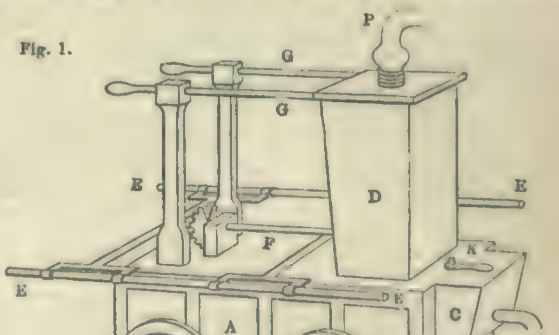
But the earliest account on which we can depend of a machine at all resembling those now in use is given by a Jesuit named Caspar Schott in 1657. This account related to a fire-engine made by Hautsch, of Nuremberg. It consisted of a water-cistern about 8 feet long, 4 feet high, and 2 feet in width; and was drawn on a kind of sledge somewhat larger than the cistern. It was worked by 28 men, and a stream of water an inch in diameter was forced, by means of this engine, to an elevation of nearly 80 feet. Schott supposed that it contained a horizontal cylinder, through which a piston worked, and thus produced a pump-like action. In 1699 the king of France gave a patent-right to Duperrier to construct fire-engines, under the name of *pompes portatives*, or portable pumps, and to keep them (17 in number) in repair and working order. Twenty-three years afterwards, the number of pumps amounted to 30, the management of which cost 20,000 livres annually.

There are two important parts of a fire-engine which do not appear to have been brought into use for some time after such machines became general: we mean the flexible hose or tube, and the air-chamber. Hautsch's engine, however, possessed the former, but not the latter. The purpose of a flexible tube is obvious, for it enables the operator to carry the stream of water in any direction from the engine; whereas without it the sphere of the engine's use is limited, from the impossibility of carrying the engine itself through narrow passages, &c. The air-chamber is a contrivance which depends for its value on the increased elasticity of air when compressed into less than its usual bulk. It is not exactly known who first applied this improvement; but an engine containing an air-chamber is stated by Perrault to have been kept for the protection of the king's library at Paris in 1684. The first introduction of them, however, for common use appears to have occurred about the year 1720, when Leupold constructed engines consisting of a copper box securely closed and well soldered: each one weighed about 16 pounds, and ejected a continuous jet of water to a height of 20 or 30 feet. This engine contained one cylinder and piston. The adaptation of leathern pipes was devised by two natives of Holland, both of whom were named Jan Vanderheide, and who were inspectors of fire-engines at Amsterdam in 1672. Five years after the invention, a twenty-five years' patent for the privilege of making those pipes was granted to them; and in 1695 sixty of them were kept in the city, of which six were to be used at each fire.

After the introduction of these engines into England, improvements were from time to time made in them, by Dickenson, Simpkin, Phillips, Furst, Newsham, Rowntree, Merryweather, Baddeley, Shand, Mason, and others; but from the time that the air-chamber was introduced the principle of construction has been nearly the same in all of them, the points of difference being principally in minor details. In briefly describing one of the old engines, therefore, on the construction of Newsham, we shall convey a general notion of the mode of action of most of them, without touching at present on the nicer points of difference.

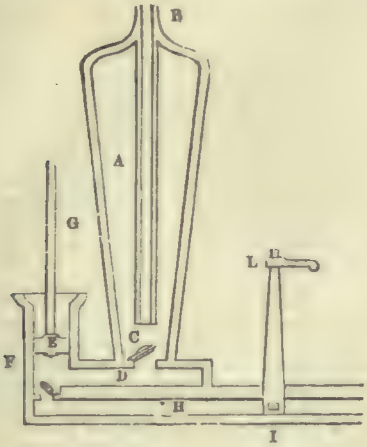
The body A (*fig.* 1.) incloses the greater part of the mechanism of the engine. Along the lower part runs a metallic pipe, into which the water flows from the feed-pipe B. If a supply of water cannot be obtained in this way, a cistern, C, is filled by means of buckets; and at the junction between the cistern and the interior pipe a grating or strainer is placed, to free the water from dirt, gravel, &c. The water having entered the interior pipe, is forced into the air-vessel by two pumps contained within the body of the box D, and from the air-vessel is forced into the pipe P, connected with the leathern hose by which the propelled water is directed to the proper point. The two pumps are worked by a double lever connected with two long handles, E E E E, which are conveniently placed for being worked by several men. The working is aided by one or two men, who stand on a cross-lever near F, and throw their weight alternately on each side, holding by the handles at G. At K, is a handle which turns a cock or valve, thereby regulating the supply of water to the interior pipe through the feed-pipe B. In *fig.* 2 we give a section through the middle of the air-chamber and one of the pump-barrels. A is the air-vessel, from the top of which proceeds nearly to the bottom a tube B C, open at both ends. The air-chamber and tube are in communication with a horizontal pipe, D, which opens by two branches into two pump cylinders, one of which is seen at F. Through this cylinder works the piston E, which is connected by the piston rod G with a toothed-wheel at the upper part; to which wheel a reciprocating motion is given by the exterior levers to which it is attached. The horizontal pipe D, besides its communication with the air-vessel and the pump-barrel, is also open to another horizontal pipe H, which is connected at the other end with the feed-pipe shown in the former figure. These communications however are closed at different parts of the operation by two

Fig. 1.



valves, one of which opens upwards from the pipe H to the pipe D; and the other also upwards from D to the air-vessel A. At the point I in the lower pipe is situated the cock, the handle of which is seen at L.

Fig. 2.



This being the relation of the parts to one another, let us now suppose the piston E and its rod G to have a reciprocating motion. The air chamber being full of air of the ordinary atmospheric density, we will suppose the piston to be drawn up to the top of the pump cylinder F. The piston draws up with it the air which the cylinder contains, and thus creates a partial vacuum beneath. The valve between the two pipes having now a stream of water pressing it upwards, while the space above it contains rarefied air only, the valve is forced open, and the pump-barrel F and the pipe D become filled with water. When the returning stroke of the lever forces the piston down to its former position, the water is driven before it into the air-vessel A. At the second upward motion of the piston a partial vacuum is again produced beneath it; but the water now contained in the air-vessel cannot return to fill that vacated space, on account of the mode in which the valve opens. A fresh supply is therefore gained, as before, from the pipe H through the valve communicating with D. This supply is, by the subsequent downward pressure of the piston, forced into the air-vessel, in the same manner as the first portion. The air in the air-vessel has no communication with the external atmosphere except through the pipe B C, which is fitted air-tight into the neck of the vessel at B. When the water ascends in this vessel above the bottom of the tube at C, the air above that level becomes compressed into a smaller space, as all escape is guarded against. With this compression its elasticity is also increased in the same ratio; and the effect of that increase is to drive the water up the tube. The velocity and height depend upon the compression; but as long as the density exceeds that of the external air, so long will the water be forced up the tube; and thus a continuous stream is insured, which is the object desired. If the condensation be carrried to a greater extent, the height to which the water will be ejected will increase in the same ratio; so that, if the bulk of the confined air were reduced to one-third, one-fourth, or one-fifth of its original bulk, the ascensive power gained would be about 66, 99, or 132 feet respectively.

Such are the simple principles of the old fire engines. It need hardly be said that improvements have since been introduced in every part. Contrivances are now used for preventing mud and gravel from entering the engine by the feed. Some engines, entirely of metal, have been made by Mr. Tilley. Merryweather's small or portable engines are provided for the special protection of public establishments and large mansions. The leathern hose or tubes, usually sewn up at the side, are sometimes fastened by means of metallic rivets. The Americans have devised a mode of weaving cotton tubes for engine-hose; a machine has been invented that will do this at the rate of 1000 feet per day; the tubes are only one-tenth the cost of leathern hose; and if two concentric tubes of this kind be cemented together with caoutchouc-solution, they are said to be even more durable than leather, and to require no oiling. Much ingenuity has been shown in devising a form of boss or nose for the end of the hose; the boss contains many small openings for the exit of the water; and Bramah, Baddeley, and other engineers, have so contrived these terminal pieces as to direct the play of the stream of water in any direction in a burning apartment. Captain Fowke's fire-engine, patented in 1859, dispenses with a cistern, and can hence be conveyed rapidly, on account of its light weight. It has a pair of single-action force-pumps, fitted with metal valves; a suction and delivery air-vessel; hose, to draw water into the pumps; and lever-handles, to force it out. It may be drawn by hand, or connected with a carriage drawn by a horse. A fire-engine of great power was made for the London Docks some years ago, with working barrels eight inches diameter; it would throw a jet eighty feet high, when worked perpendicularly. Many other fire-engines of great magnitude have since been constructed.

Mr. Braidwood, superintendent of the London Fire Brigade Establishment, read a paper before the Society of Arts, in 1856, in which he said:—"The description of fire-engines found to answer best in the metropolis are those with 7-inch barrels and 8-inch stroke, throwing, at the ordinary rate of working, about 90 gallons of water per minute. If a larger engine is thought desirable, two of these can be easily joined together in one stream, giving 180 gallons per minute. This size is preferred, because the weight, with hose, implements, firemen, and driver, is about 30 cwt., which is as much as two fast horses can manage for a distance under six miles. It is not often that the engines are required to travel further than this; when they are, four horses are used. For some years past, a hand-pump has been carried with each engine; they having been found of the greatest service in keeping doors, windows, &c., cool. They throw from 6 to 8 gallons per minute, to a height of 30 or 40 feet, and can be used in any position. The idea of these hand-pumps was taken from the old-fashioned squirt or hand-engine."

Down to the year 1825 all the Fire Insurance Companies of London had their separate establishments of fire-engines; but in that year the Sun, the Union, and the Royal Exchange Companies joined their fire-engine establishments, which were placed under one superintendence. Soon afterwards the Atlas and the Phœnix Companies joined the association. The advantage of this combined system of action having been proved, most of the remaining companies joined in 1833, and formed a new association, which was to be managed by a committee, formed by one member from each of the associated companies. London was divided into a certain number of districts, in each of which were two or more stations provided with engines. The plan has worked well: more companies have joined the association; and it is found that all are benefited. The firemen are formed into a corps, called the *fire-brigade*, which is under the efficient control of Mr. Braidwood, as superintendent. The men are clothed in a uniform, with stout helmets; and a certain number of them at each station are ready at all hours of day or night. Each company pays its quota towards the expenses of the fire-engine establishment. A very marked improvement has resulted in the capability and working of the engines. It may here be observed that, in by-gone years, the parishes of London provided fire-engines, under the compulsory provisions of two Acts passed in 1768 and 1778. About 300 of these small parish-engines still exist, but they render very little assistance at fires; it is found that the insurance companies, with their well-organised brigade, manage the business much better. The brigade now possesses about 30 large engines, and 10 or 12 smaller drawn by hand. It has a well-drilled staff of upwards of a hundred engineers, sub-engineers, firemen, and drivers. There are about twenty stations in the Metropolis, each with one to four engines, and a proportionate staff.

The remarkable aptness and celerity of the men composing the London Fire Brigade enable them to render an amount of service truly surprising. The police, cabmen, and poor persons out at night, are always ready to give notice at the engine-stations when a fire occurs—since they receive a fee for so doing; and thus the necessary intelligence is conveyed as quickly as in continental cities, where there are night-watchmen on elevated buildings to look out for fires. When the superintendent or foreman at any one of the twenty engine stations hears of the locality of a fire, five minutes' time is deemed sufficient to horse and away. Each of the large engines carries an engineer, four firemen, and a driver, besides the following apparatus:—several lengths of scaling-ladder, each 6½ feet long, all of which may be readily connected end to end, forming in a short space of time a ladder of any required height; a canvas sheet, with 10 or 12 handles of rope round the edge of it, to serve as a fire-escape; one 10-fathom and one 14-fathom piece of 2½ inch rope; six lengths of hose or leathern water-pipe, each 40 feet long; two branch-pipes, one 2½ feet, and the other 4 or 5 feet long, with a spare nose-pipe; two 6-feet lengths of suction-pipe; a flat rose, stand-cock, goose-neck, dam-board, boat-hook, saw, shovel, mattock, pole-axe, screw-wrench, crow-bar, portable cistern, two dog-tails, two balls of strips of sheepskin, two balls of small cord, instruments for opening the fire-plugs, and keys for turning the stop-cocks of the water-mains—the whole, with the men and the engine, weighing nearly 30 cwt.

On the Continent, and in America, the fire-engines are not managed, as in England, by fire-insurance companies; it is with them more of a government affair. In Paris, there are seven times as many firemen (*sapeurs-pompiers*) as in London, notwithstanding the smaller area and population; and yet the by-standers are compelled by law to aid in working the engines. In the United States, fire-companies of volunteers are formed in many of the towns; the members receive, not pay, but certain immunities from taxation and militia service. The annual parade-day of these companies is quite a fête, to which the fire-companies of other towns are invited, and at which competition trials of engines are made. Each company wears its own distinct uniform. Sometimes 36 companies of 50 men each have met. The prizes are usually awarded to the firemen of those engines which discharge a jet of water to the greatest height; in recent years a height of no less than 150 feet has been reached, by an engine with 10-inch cylinder. During the continuance of the Paris Exhibition in 1855, the engine-makers of

London, Paris, Canada, and the United States, placed between twenty and thirty large engines in competition, to test their powers for the satisfaction of one of the juries.

A few words must be said concerning the *steam* fire-engine. This was first employed at a fire at the Argyll Rooms, in London, in 1830, and displayed great power in throwing the water against the building. The furnace and boiler of this engine were similar to those of the 'Novelty,' a locomotive engine constructed by the same engineer for railway traffic. The pipe by which the water was jetted turned on a swivel, by which means the stream could be directed to any quarter. The cylinders were placed horizontally, and the steam-piston was connected with the water-pump plunger by a rod working through two stuffing boxes. This engine, the total weight of which did not exceed 45 cwt., consumed 3 bushels of coals in 5 hours, by which expenditure it was enabled to throw out from 30 to 40 tons of water per hour, which it propelled to a height of upwards of 80 feet, and on one occasion to 90 feet. Another engine, on the same construction, by Mr. Braithwaite, possessed 10-horse power (the former being about 6), and ejected the enormous quantity of 90 tons of water per hour. In 1832 a steam fire-engine was made for the king of Prussia by the same engineer, in which the steam could be got up in 20 minutes to a pressure of 70lbs. on the square inch. This engine ejected the water through a pipe 1¼ inch in diameter to the height of 115 or 120 feet: the number of strokes of the piston was 18 per minute, and the body of water ejected about 1¾ ton in that time. The power of steam was likewise applied to a *floating* fire-engine by Mr. Braithwaite, the machinery of which is so constructed, that the power of the engine can be at once changed from propelling the vessel to working the pumps, and thus do double duty. The London Fire Brigade Committee have recently turned their attention to this subject. Their first attempt was to alter a floating fire-engine which had been worked by manual power; and this was so well done, that the engine poured out 700 gallons per minute under a pressure of 70 or 80 lb. on the square inch. Another was thereupon constructed capable of throwing 1400 gallons per minute, and of moving at the rate of eight miles an hour, when propelled by the reaction of two jets 10 inches in diameter, driven by one of Appold's pumps. The vessel built for these engines is 130 feet long, with pumps and engines placed on the starboard and larboard sides of the midships. At Cincinnati large steam fire-engines have been for some years used; and the good service they render partly induced the London companies to revive and improve upon the old invention of Braithwaite. Competition trials of steam fire-engines have taken place in New York; one of them is said, at an extensive fire, to have poured out 15,000 barrels of water in 8¼ hours. Messrs. Shand and Mason have recently produced a new steam fire-engine in London, for use on land.

FIRE-ESCAPE. Numerous contrivances have been brought under public notice from time to time for saving the lives of persons who may be in a building while it is burning. Mr. Maseres devised a kind of chair of straps, by which a person could lower himself from a window. Mr. Davis, in 1809, proposed the use of three ladders, which might draw out like a telescope, and might reach from the ground to the upper windows of a house. Mr. Young, in 1813, contrived a sort of rope-ladder, with iron rounds of very flexible construction. Mr. Braby, in 1816, invented a sort of long pole, down which a car or chair might travel from a window to the ground. Mr. Witty, in 1820, introduced a sort of bag or case, which may be lowered from the sill of a window by ropes governed by a person seated in the bag. About 1835, Mr. Ford recommended the use of a long pole, at the upper end of which is tackle for lowering persons from a window; and soon after, Mr. Merryweather contrived a series of short ladders, which fit on to each other end to end, and can be elevated to a considerable height quickly.

But the fire-escape which has come most into use in London is a wheel-carriage supporting a lofty canvas shoot or trunk, attached to a ladder or frame; when placed up against a house, a person can get into this trunk from a window, and slide safely down to the bottom, with the aid of some ingenious mechanism attached to the frame. Many such machines are kept in public places in London during the night, attended by men whose business it is to wheel the machines to any spot where life is endangered by fire, and to work the machines.

A Report was presented to the city corporation in 1840 from the police commissioners, descriptive of thirty plans for fire-escapes, which had been proposed by different parties. They were of three classes:—1st. Machines intended for domestic use only, to be resorted to by inmates of houses in cases of fire; 2nd. Machines to be used from the outside, and made to combine the security of property with the protection of persons; 3rd. Machines exclusively for the protection of life from fire, to be used out of doors under the responsible direction of the police. Among the thirty were Davis's effective but rather ponderous machine; Wivell's, with the canvas trunk; and Gregory's sliding ladders on a carriage. It was considered that, whichever may be the best form in wide thoroughfares, the common fire-ladders carried with the engines of the London Brigade are the most generally useful in courts and confined situations. A suggestion was made in 1858, that it would be a good plan if in every house was kept a strong board with a hand-rail, and a hook at each end; by hanging one end outside the window of a burning house, and the other to the window of an adjoining house, a temporary bridge or balcony might be formed. Independent of other difficulties, however, there would always be the uncertainty of such a contrivance being in the right place at the right time. Another suggestion has been made, that each street or group of houses should possess a wire basket; that there should be a bracket fixed at the top of every house-front, projecting two feet; and that the police should be provided with some kind of rocket to send a rope over the bracket, and thereby haul up the basket. A third suggestion, of recent date, is that of Mr. Meakin; he proposes to fix two wire-ropes to strong hooks in the front wall of a house, to raise a kind of cradle on these ropes by means of pulleys, and then to govern the descent of the same cradle by the same ropes and pulleys.

None of the modern suggestions, however, as remarked above, are regarded as of equal value with the long ladder and canvas bag, used by the Society for the Protection of Life from Fire. The services rendered by this society can best be shown in reference to the nature and extent of London fires. Mr. Fothergill, of the Westminster Insurance Office, read a paper before the Institute of Actuaries in 1857, in which he presented a tabular view of all the London fires for twenty-four years, from 1833 to 1856. His object was to ascertain, if possible, the relative intensities of the causes of fire in each particular trade or occupation; with a view of rendering the return of annual fires by the London Fire Brigade Establishment in some way useful to the office-inspectors and surveyors of risks. His labours were much thwarted by the fact that two-thirds of all fires are attributed to "causes unknown." In those 24 years there had been 17,816 fires in London, or 742 per year on an average, or about 2 per day. Of these, in about 4 per cent. the premises were "totally destroyed;" 30 per cent. "much damaged;" and 66 per cent. "slightly damaged." Among the assigned causes of the accidents, some of the most peculiar were "thawing water-pipes"—"bottle of whiskey burst"—"sealing a letter"—"frying fish"—and "hunting bugs." The extent of the insurance principle may be illustrated in reference to the year 1856, when there were 1115 fires in London; of these, 318 had the buildings and contents insured, 106 the buildings only insured, 344 the contents only insured, and 347 wholly uninsured.

The society above named has provided fire-escapes in various parts of the metropolis. The operations first commenced in 1836, since which time fire-escapes have been established in new districts every year. There are now upwards of 70, situated about half-a-mile apart, each attended throughout the night by a conductor. Of the total number of fires (1114) in 1858, more than 500 were attended by the society's fire-escapes, and 57 lives saved by their means. At one of these fires one man saved no fewer than 9 lives. In the preceding year (1857) the society's men saved 73 lives; and in the whole period of operations 497,—a useful work for a society resting on no other basis than that of private subscriptions. The society has published the following description of the fire-escape employed, with sundry improvements lately introduced: "The main ladder reaches from 30 to 35 feet, and can instantly be applied to most second-floor windows by means of the carriage-lever. The upper ladder folds over the main ladder, and is raised easily into position by a rope attached to its lever-irons on either side of the main ladder; or, as recently adopted in one or two of the escapes, by an arrangement of pulleys in lieu of the lever-irons. The short ladder, for first-floors, fits in under the carriage, and is of the greatest service. Under the whole length of the main ladder is a canvas trough or bagging made of stout sail-cloth, protected by an outer trough of copper-wire net, leaving sufficient room between for the yielding of the canvas in a person's descent. The addition of the copper-wire is a great improvement; as, although not affording an entire protection against the canvas failing, it in most cases avails, and prevents the possibility of any one falling through. The soaking of the canvas in alum and other solutions is also attended to; but this, while preventing its flaming, cannot remove the risk of accident from the fire charring the canvas. The available height of these escapes is about 45 feet; but some of them carry a short supplementary ladder, which can be readily fixed at the top, and which increases the length to 50 feet."

FIRE, GREEK, an invention of the middle ages which was often employed in the wars of the Christians and Saracens. This subject has given rise to much inquiry and excited much discussion; the obscurity by which it is enveloped has been greatly increased by many causes, and especially by the love of the marvellous.

According to Gibbon the deliverance of Constantinople in the sieges of the 7th and 8th centuries "may be chiefly ascribed to the novelty, the terrors, and the real efficacy of the Greek fire. The important secret of compounding and directing this artificial flame was imported by Callinicus, a native of Heliopolis in Syria, who deserted from the service of the caliph to that of the emperor."

It is justly observed by Gibbon ('Dec. and Fall, ch. 52), that "the historian who presumes to analyse this extraordinary composition should suspect his own ignorance and that of his Byzantine guides, so prone to the marvellous, so careless, and in this instance so jealous of the truth. From their obscure and perhaps fallacious hints, it should seem that the principal ingredient of the Greek fire was naphtha, or liquid bitumen, a light, tenacious, and inflammable oil which springs from the earth, and catches fire as soon as it comes in contact with the air. The naphtha was mingled, I know not by what method or in what proportion, with sulphur and with the pitch that is extracted from evergreen firs." One of the properties here stated to belong to naphtha is well known to be, and indeed is, obviously incorrectly ascribed to it; if it were spontaneously inflammable it could not even be collected, and of course could not be mixed with the other ingredients which are named. Whatever may have been the precise nature of the mixture, the account of its effects, from which somewhat of the marvellous must be deducted, is thus strikingly portrayed by Gibbon: "From this mixture, which produced a thick smoke and a loud explosion, proceeded a fierce and obstinate flame, which not only rose in perpendicular ascent, but likewise burnt with equal vehemence in descent or lateral progress; instead of being extinguished, it was nourished and quickened by the element of water; and sand, urine, or vinegar were the only remedies that could damp the fury of this powerful agent, which was justly denominated by the Greeks the *liquid* or the *maritime* fire. For the annoyance of the enemy, it was employed with equal effect by sea and by land, in battles or in sieges. It was either poured from the ramparts in large boilers, or launched in red-hot balls of stone and iron, or darted in arrows and javelins, twisted round with flax and tow which had deeply imbibed the inflammable oil. Sometimes it was deposited in fire-ships, the victims and instruments of a more ample revenge, and was most commonly blown through long tubes of copper, which were planted on the prow of a galley, and fancifully shaped into the mouths of savage monsters, that seemed to vomit a stream of liquid and consuming fire." According to Gibbon, the secret of the Greek fire was confined above 400 years to the Romans of the east; it was at length either discovered or stolen by the Mohammedans, and in the holy wars of Syria and Egypt they retorted an invention contrived against themselves on the heads of the Christians. The *feu Grégeois*, as it is styled by the more early of the French writers, is thus described by Joinville: "It came flying through the air, like a winged long-tailed dragon, about the thickness of a hogshead, with a report of thunder and the velocity of lightning; and the darkness of the night was dispelled by this deadly illumination." The use of Greek fire was continued to the middle of the 14th century, when the more efficient employment of gunpowder was substituted. When Ypres was besieged by the Bishop of Norwich in 1383, the garrison defended itself with Greek fire. In a curious paper on the subject of Greek fire by the late Dr. MacCulloch ('Royal Inst. Journal,' vol. xiv.), he remarks that very different things were known by one name; and he supposes the various projectile means and combustibles employed to have been essentially different.

FIREPROOF CONSTRUCTION. A building is said to be *fireproof*, when it is constructed of incombustible materials; but it is essential to observe, that the danger arising from fire cannot be obviated entirely, even by the most theoretically or practically incombustible construction; and that consequently it is necessary, not only to observe the ordinary precautions against the destruction by fire of goods kept in such buildings, but also to guard against the effects of extraordinary heat upon the really incombustible materials of which the buildings themselves are formed. In the following notice, therefore, a description will be given of the materials which are the most fitted for the erection of fireproof buildings; and attention will subsidiarily be called to the danger and inconveniences to which they are exposed in actual practice.

The conditions required to be fulfilled by the materials to be employed in the erection of fireproof buildings are, that they should not only be unable to burn under the action of ordinary heat; but that they should also be, as far as possible, non-conductors of heat; that they should not expand or contract in a marked degree under the influence of changes of temperature, and that they should neither be exposed to fuse, nor to undergo chemical decomposition, when submitted to the action of fire. Of course all woods are excluded from the class of incombustible materials; but it must be evident, from the enumeration of the conditions those materials are required to fulfil, that the plasters, cements, limes, some varieties of bricks, and stones, cannot safely be trusted when they are likely to be exposed to great heats; and that the metals are equally objectionable, because they not only transmit heat readily and alter greatly in their dimensions, but also because sudden and great changes of temperature affect their powers of resistance, and even occasionally cause them to change their form entirely. The plasters and limes used in building owe their strength to the molecular adhesion originally produced by the solidification which takes place in the course of their hydration, and is subsequently increased by the gradual absorption of carbonic or sulphuric acid gas from the atmosphere. A very low temperature, comparatively, will suffice to destroy this state of combination, and to drive off both the gases and the water of crystallisation to such an extent as to destroy the cohesion of the mass. It is for this reason that the French plaster floors, or the English concrete floors (whether made with a lime or a cement base), are not able to resist the effects of great fires, although they may be sufficient to render ordinary dwellings practically fireproof; and for the same reason, brick vaulting itself is not entirely to be relied upon, when the area it covers is great, and there may be large quantities of combustible materials stored beneath it. Of the building stones, it would appear that the sandstones are more adapted for the purposes of fireproof construction than the limestones, because the latter become calcined under great heats; nevertheless, both limestones and sandstones are injuriously affected, both by the fire and by the water which is so profusely used on the occasions referred to. The sudden contractions produced by the application of cold water cause even granites themselves, about the most infusible of building materials, to fly, as workmen say, or to crack; and the same danger exists wherever metals are employed, even in a greater degree than when the less rapidly conducting materials are used.

It follows, from these considerations, that the security offered by any system of fireproof constructions must depend greatly upon the extent of the conflagration which may take place in them. As a fireproof building ought to be without any communication with surrounding buildings, and to have very small openings to the air in the majority of cases, it really acts in the manner of a retort upon the goods which may happen to be in combustion in its interior. It therefore is essential that the cubical capacity of any isolated incombustible compartment or building should not be large enough to allow a fire to take place which should be able to destroy the physical properties of the building materials employed; and it is to the neglect of this simple precaution that we may attribute the fact that whenever a fire does take place amongst the goods stored in incombustible buildings, the destruction of the goods themselves is entire, and that the stability of the building is so likely to be compromised. Some goods, such as cotton, wool, &c., are liable to spontaneous combustion; and if such goods should be stored in large quantities in one building, the security afforded by the supposed fireproof character of the materials of the latter will too often be found to be fallacious. Some of the most destructive fires have actually taken place in fireproof buildings; and nothing can be more striking than to observe the unaccountable changes of form produced in the iron, stone, or brick, exposed to the action of large masses of incandescent materials thus enclosed. Cast iron appears to be far more injuriously affected in these cases than wrought iron, especially when it is likely to be suddenly chilled by the cold water pumped upon the burning goods. Wrought iron, however, loses its elasticity when heated, and is exposed to change its form under the action of loads it would otherwise have easily supported.

These remarks apply especially to warehouses; but in ordinary house or shop construction it rarely happens that a sufficient quantity of goods is contained in any one compartment of the building to entail any extraordinary danger. If, therefore, the walls of such houses be built of good brick or stone; if iron be used instead of wood for girders, lintels, bressummers, &c.; if the roof be entirely of metal, and the floors of either brick-work, tiles in cement, stone landings, or of plaster or concrete; the houses will be, for all practical purposes, fireproof. These materials are, however, all of them good conductors of heat; and, as such, they require, in dwellings, to be covered with wood, or some other material which should be able to obviate the unpleasant feeling produced by their being exposed. The danger of the combustion of such woodwork may be materially diminished by the application of a soluble glass to all the exposed surfaces; and care should be taken that none of the wood runs so far into the solid walls as to affect their stability, either in consequence of its being burnt out, or on account of the chemical changes produced by the heat. The resinous woods being more rapidly inflammable than oak, or the harder woods, such as mahogany, teak, rosewood, &c., are less fitted for the purposes of lining fireproof structures than are the latter; and it is perhaps on account of the general use of oak floors in Paris that so few fires occur in that town, in comparison with those which occur in London, where fir floors are almost exclusively used. It may be added, that one of the greatest sources of danger in ordinary house building arises from the use of wooden staircases, which serve to conduct the fire from one floor to another. As a general rule, moreover, it will be found that the thickness of party walls which is requisite to ensure the statical stability of a building will be sufficient to prevent the communication of any ordinary fire from one house to another: provided always that no timbers be allowed to be inserted in such walls, or at least that solid non-combustible materials of at least nine inches in thickness shall always be placed between the ends of the timbers thus let in. Great care should be taken, when artificial methods of warming are adopted, to isolate the timbers or joiners' work from the pipes or passages by which the heat is distributed; for the effect of the proximity of wood-work to such heat passages is to dessicate the wood thoroughly, and to render it highly inflammable. The same remark would of course apply, *mutatis mutandis*, to the combustion of gas near wood-work; and it is desirable in all these cases that a sufficient non-conducting cushion of air should be, as it were, interposed between the source of heat and the wood-work.

FIREPROOFING. In this article we shall briefly describe three modes of shielding combustible articles from the ravages of fire, under the sub-headings *Fireproof Repositories*, *Fireproof Woodwork*, and *Fireproof Textile Goods*.

Fireproof Repositories.—By this we do not mean houses or buildings, rendered fireproof by peculiar modes of construction; these are treated in another article. [FIREPROOF BUILDINGS.] We speak of iron chambers, coffers, or boxes, for containing valuable property. It was not until the present century that such receptacles were regularly and systematically made. A few may have been constructed as special examples of ingenuity; but the manufacture had not yet become a regular branch of trade. The old treasure-receptacles were oak chests, secured by one or more locks, or brick or stone closets, with wooden doors studded with nails, and fastened by locks, or staples and padlocks. The crown jewels of Scotland were placed in a strong oak chest in the year 1707; it had three locks, and when required to be opened in presence of a body of royal commissioners in 1818, it had to be forced, on account of the loss of the key or keys. Iron coffers of elaborate construction were known on the Continent before being common in England,—possibly on account of the system of hoarding treasure, more customary in countries where commercial enterprise is languid. Wolverhampton, Birmingham, and Coalbrook Dale began the manufacture of cast-iron safes; London alone made those of wrought iron till 1835, since which year they have been made also in the north. These safes, however, were not in the first instance put forth as fireproof; there was nothing to prevent them, when red-hot, from burning the papers and charring the parchments inclosed in them. It was in 1834 that the fireproof principle appears to have been first adopted, under Marr's patent. Since that date, Bramah, Chubb, Milner, Hobbs, Price, Tann, and other manufacturers have brought great ingenuity to bear on this subject. There are several requisites for a good fireproof safe. The iron should be of such a thickness as to prevent the safe from being broken open by violence, or injured by a fall or other casualty during a fire. The door should be so closely fitted that no forcing instrument could be introduced between its edge and the framework into which it closes. The iron plates should be so prepared as to resist the action of drills, whether made for the purpose of taking out the small lock or of inserting gunpowder to shatter it. The large lock should be so made that, even if holes were drilled through the door, no space would be found inside the case to contain sufficient gunpowder to explode it. The case containing the lock should fit the interior of the safe as tightly as possible, to exclude the external heat in case of fire and the escape of the moisture from the fire-resisting composition within. The inside case, forming chambers for containing the fire-resisting substance, should fit the inside of the body tightly, to prevent the undue escape of the vapour when in a fire; this case, also, should be so secured to the outer frame that no violence exerted on the door would force the removal of the lining or casing. The fire-resisting composition should be of such a nature and should be so placed as not to exert any injurious effect upon the iron when heated. It need hardly be added, that the large lock which closes the door, and the small lock which secures the bolt, should be free from liability to disarrangement, likely to wear well, and not easily picked. All the modern fireproof safes contain a sort of lining of fireproof composition, which has a remarkable effect in arresting the progress of heat from without inwards. Of course no safe could resist an unlimited heat for an unlimited time; but the modern makers are very successful in manufacturing safes which will preserve their contents unharmed during the destruction by fire of the building in which the safe is placed. There is an absorbent substance, such as sand or sawdust, and there are small vessels containing some kind of liquid; the heat from an external fire, acting on the liquid through the iron, bursts the vessels, saturates the absorbent substance, and greatly retards the heating of the interior. Some of the safes are painted on the inside with a peculiar composition, to prevent the metal from being oxidised or corroded by the action of acids employed to produce the moisture; and the exterior of the iron is case-hardened, or rendered like steel, to enable it to resist the action of drilling-intruments. Triple thicknesses of iron, mica linings, vitreous glazings,—all are used in different forms of safe; and the absorbent composition used for a stuffing or damper exhibits great variety,—burnt clay, powdered charcoal, dust, fragments of stone, baked wood ashes, coarse sand, small gravel, sawdust, bone-dust, ground alum, gypsum, Austin's cement, combined two or more together, with or without provision for moistening them when heated.

Some of these fireproof receptacles have recently been constructed of great magnitude. One was made by Messrs. Chubb in 1858 for the Vancouver branch of the Bank of British North America. It was 7 feet high, 9½ feet deep, and 7 feet wide. It was made of wrought iron, lined with a fire-resisting composition. It was, in fact, a chamber, containing nineteen separate and distinct lock-up safes, besides shelves for books and papers. On the exterior it had two large folding-doors, having three detector locks, and throwing thirty bolts all round. The various pieces, weighing 14 tons in all, were sent out separated, to be built up at the place of destination. A partner in this firm, after the disastrous loss of the gold-laden ship Royal Charter, wrote to one of the public journals in the following terms:—"In ocean-ships the bullion-room is usually formed by lining some nook or corner with strong iron-plates, bolted to, or forming part of, the ship; so that if the vessel gets on shore and breaks up, the bullion-room necessarily goes to pieces with it, and the contents are dispersed. I would suggest that these safes should not be in any way connected with or fixed to the ship. In case of a wreck or breaking up of the vessel on shore, the safe would go to the bottom, preserve its contents intact, and be readily recovered. As a safe four feet square will hold more than 2,000,000*l.* sterling, very little space would be interfered with."

A London solicitor, in a letter to the 'Times,' has pointed out the desirability of having, somewhere near the courts of law and inns of court, a public or joint-stock institution for the safe custody of valuables from fire and depredation. "The main features of my plan," he explained, "would be to erect two or three fireproof buildings in so many localities in London, most convenient to professional gentlemen and others who may avail themselves of these advantages; and to have in each building separate strong rooms for any persons wishing to have the exclusive use of them; and also other places for depositing deeds, securities, plate, &c., on the responsibility and under the guardianship of the managers." It is supposed, according to this suggestion, that an adequate rental would willingly be paid for such fireproof strongholds.

Fireproof Woodwork.—In the article ANNIHILATOR, FIRE, a description is given of a mode of extinguishing fire by means of chlorate of potash mixed with sugar—not used as a liquid to protect woodwork, but as a gas which stifles the flame. We have now to notice a process which has recently occupied much attention. Many liquids have been devised from time to time, for making wood more or less fireproof. A mere coating of lime-wash will do something towards this end; and a wash or cream of clay in water will act nearly in the same way. In Maugham's patent process, dry wood is saturated with an aqueous solution of phosphate of soda and muriate or sulphate of ammonia; the theory or expectation being, that a decomposition will ensue, followed by an evolution of ammoniacal vapour, and the formation of an incombustible coating on the surface of the wood. Jackson's patent consists in the application of a solution of salts of zinc and ammonia. Salomon's patent consists in a peculiar application of two solutions to the surface of wood; the first consisting of sulphate of alumina, glue, and water; and the second of chloride of calcium, glue, and water.

The substance which is now attracting most notice, in connection with this subject, is silicate of soda. Mr. Abel, chemist to the War Department, and Mr. Hay, chemist to the Admiralty, made experiments on this salt in 1857. A wooden hut, similar in construction to those at Aldershott Camp, was set up at Woolwich Marshes. The immediate purpose in view was to test Phillips' Fire Annihilator; but advantage was also taken of the opportunity to try the efficacy of the silicate of soda as a protector. The officers of the Royal Engineers suggested that if a *part* of the hut were thus treated, the result might afford materials for comparison. This was done. One portion of the hut was painted inside and out with a mixture of lime and alum; this was not found to act as a sufficient protector against fire. Another portion was then painted inside and out, three times, with a solution of silicate of soda. Unfortunately for the fairness of the experiment, the building was constructed with a double boarding; so that it was only possible to coat or impregnate each plank on one side. Nevertheless, the value of the silicate was established beyond a doubt. A large heap of shavings was lighted in the interior of the hut, against the coated portion of the woodwork. The flame played fiercely against the timber for some minutes, but only succeeded in kindling the edge of one plank; and even that did not blaze, but only smouldered for a short time. By the heat of the fire the salt was drawn to the surface of the wood, and fused, forming a glaze upon it. Subsequently, when the whole hut was destroyed by fire, after unsuccessful attempts to extinguish it by the annihilator, although the fierceness of the flame was such that few materials could have withstood it, yet several planks remained of the exterior coated portion. Upon examining these planks, the unprotected surfaces were found to be completely charred; but this charring had extended only to those parts which had not been touched by the silicate. So far as experiments have yet gone, this salt appears to be the most convenient and effective known for the purpose.

Fireproof Textile Goods.—Attempts are now being made to impart something of the nature of non-inflammability to the muslin and other light materials of which ladies' dresses are made. Very lamentable calamities from fire have drawn attention to the subject; and at the Aberdeen Meeting of the British Association, in 1859, certain experiments were described which had been made by Messrs. Versmann and Oppenheim. It has long been known that cotton and linen fabrics may be partially protected from fire by a solution of alum or of common salt; but the alum weakens the fibres, and the salt makes them harsh and crisp—faults which greatly lessen the value of the processes. Experiments showed that borax will exert a considerable preservative effect, but that the material is weakened thereby as with alum. It was next found that phosphate of ammonia exerts the preservative effect without that of weakening; but here occurred a new difficulty: the salt becomes decomposed under the heat of the laundress's iron. Sulphate of ammonia, only one-fourth the price of the phosphate, was next tried; it had most of the merits and the one defect of its predecessor. Messrs. Versmann and Oppenheim at length hit upon the tungstate of soda, as a salt which, in solution, imparts a considerable degree of non-inflammability to textile or woven fabrics, without weakening them, or rendering them harsh and stiff, and also without liability of having the preservative properties removed by heat or by washing. Since the Aberdeen meeting, the inventors have arrived at a conclusion that the cheap sulphate of ammonia will suffice in factories on general woven goods; but the tungstate of soda is better for domestic use, where the fabric is likely to be afterwards ironed. It is evident, from this enumeration of chemical agents, that others of superior efficacy may probably be discovered. A new process has just been announced, the invention of M. Carteron, of Paris, which will render silk as well as cotton and linen fabrics incombustible, but the method has not been published.

FIRE SHIPS. Among the peculiarities of naval warfare may be instanced the use of fire ships, a class of vessels which are so fitted with inflammable and combustible substances, as to take fire in all parts simultaneously on the lighting of an attached fuse, the length of the fuse being adapted to the occasion, and so as to allow sufficient time to elapse after ignition to enable the firing party to effect a safe retreat from the conflagration.

Fire ships are at all times a formidable means of attack, but especially so when darkness or fog favours their employment. They are used principally in rivers or roadsteads against ships at anchor. The Chinese in the late war showed considerable ingenuity in availing themselves of this mode of surprise and attack, in which so little exposure of life on their side, enabled them to threaten with destruction a more powerful enemy; and but for great vigilance on our part, much disaster to our ships must have resulted. The nature of improved armaments, however, tends materially to protect ships at anchor from attempts of this kind; for immediately on the detection of a suspected fire ship, the increased precision of aim, the heavier weight of shot, and the progressing improvement in naval tactics now developing, will enable a threatened ship rapidly to destroy and sink any of the class of vessels generally used as fire ships, or will disperse into fragments the framework and materials of fire rafts.

So long as 150 years since, fire ships formed part of the regular establishment of the naval defences of the kingdom. In the 'Navy List' of 1710, we see the names of five of these vessels, each of which was armed with 8 guns, to be used either for ordinary battle, or in setting fire to an enemy, as opportunity might offer. Of late years, however, their use has been confined solely to the defence of invaded coasts. No ships of this class are now to be found in the English navy. Every gunner in the sea service is trained according to an approved system on board H.M.S. Excellent, to so dispose of combustible matter, fuses, &c., as to readily convert any vessel into a fire-ship.

(*Magnæ Britanniæ Notitia*; Sir Howard Douglas *On Naval Warfare with Steam, &c.*)

FIRKIN, a measure of ale, beer, and some dry commodities now disused. Eight gallons of ale, soap, or herrings, made a firkin, and nine gallons of beer. But by a statute passed in 1689, the distinction between the firkin of ale and beer was abolished, except only in London, and eight and a half gallons were declared to make a firkin. In 1803 the ale and beer measures were ordered to be assimilated, and the firkin now contains nine gallons.

FIRM. [Partnership.]

FIRMA'N or **FIRMAU'N**, is the name of the decrees issued by the Turkish Sultan, which are signed with his own cipher or signet. Such are the firmauns by which he appoints the various pashas and other great officers of the state. Firmaun is also the name of a kind of passport which the pashas are in the habit of granting to travellers, especially Europeans, by which they enjoin the subordinate authorities to give the bearer protection and assistance. The "firmaun of death" was a sentence of summary execution issued by the sultan against a pasha, the written order for which was entrusted to a chiaous, or state messenger, whose duty it was to see it executed.

FIRST FRUITS (Primitiæ), the profits of every spiritual living for one year, according to the valuation thereof in the king's books [Annates]. They were claimed by the pope throughout Christendom, his claim being first asserted in England in the reign of King John, and then only so far as related to clerks whom he appointed to benefices. Afterwards, by Pope Clement V. and John XXII., about the beginning of the 14th century, they were demanded from all clerks, by whomsoever presented. By 25 Henry VIII. c. 20, and 26 Henry VIII. c. 3, first fruits and tenths [Tenths] were given to the king. In the thirty-second year of the same reign a court was erected for the management of them, but it was soon after abolished. Queen Anne gave up the first fruits to be applied towards the augmentation of small livings. [Benefice.]

First fruits arising in Ireland were by Geo. I. c. 15, to be applied for the same purpose; but by the 3 & 4 Will. IV. c. 37, the payment of first fruits in Ireland is abolished.

FISC, FISCUS, was the name given under the Roman empire, and afterwards in the monarchies which rose on its ruins, to the private treasury of the sovereign, as distinguished from ærarium, or the treasury of the state. The fiscus was chiefly replenished by fines and confiscations, and unclaimed property of deceased persons: the taxes and other revenues of the country were paid into the ærarium. Under absolute monarchies, however, the two treasuries have been often confounded both in name and in reality. Under the feudal system, fiscus regius and fiscales terræ signified the domains of the crown, and the peasants attached to those domains were called fiscalini. Fiscus by degrees came to be used figuratively for the rights of the crown in civil as well as criminal matters, and the king's attorney was called procurator fisci, procureur fiscal in French, avvocato fiscale in Italian. Fiscus, in the sense of "feudum regium," or fiefs granted by the crown, was contrasted with proprietas, or an allodial estate. The word fiscus meant originally a basket or frail in which the moneys of the prince were collected. (Ducange.)

FISHERIES are localities frequented at certain seasons by shoals or great numbers of fish, where they are taken upon a large scale. The right of frequenting these fishing-grounds has frequently been matter of dispute between governments, and sometimes the subject of treaties; while exclusion from them, or invasion of presumed exclusive rights to their enjoyment, has been the cause of warlike preparations. The principal kinds of fish which are the objects of these systematic occupations are whales, cod, ling, hake, herrings, lobsters, mackerel, oysters, pilchards, salmon, anchovies, sardines, sturgeon, and tunny. With the exception of the four last-named descriptions, the fishermen of this country are engaged in the taking of all these fish, and pursue their calling to an extent which makes each an important branch of national industry. The quantity of other fish taken by British fishermen is in the aggregate exceedingly great, and furnishes constant employment throughout the year to a great number of men on almost every part of the coasts of Great Britain and Ireland; but it has not been usual to apply the word fisheries otherwise than as we have already mentioned.

Of the British fisheries, some are carried on in rivers or their æstuaries, and others in the bays or along the coasts. Our principal cod-fishery is on the banks of Newfoundland; and for whales our ships frequent the shores of Greenland, Davis's Straits, and the South Seas. Of late, whale-fisheries have also been carried on near the shores of Australia and of the Cape of Good Hope.

The taking of herrings was extensively pursued in Scotland in the ninth century, and continued until the Convention of Royal Burghs prohibited the exportation of fish before the resident population was supplied at a stipulated price. In consequence of this interference, many of the fishermen abandoned the pursuit at home, and settled in Holland—a circumstance which first drew the attention of the Dutch to the value of the Scotch fisheries. Several enactments were passed under James III., IV., and V. of Scotland for the promotion of the fisheries; and James VI., before his accession to the English throne, directed the building of three towns for the same purpose; but this measure failed of success. In 1633 Charles I. ordained "An Association of the three kingdoms for a general fishery within the hail seas and coasts of his majesty's said kingdoms," but the breaking out of the civil war put an end to this scheme. In 1654 the government, in order to give protection to the fisheries, remitted in favour of Sir Phineas Andrews, who had embarked in the same, the salt duties and "customs, and excise duties upon all naval necessaries;" besides which, voluntary collections were made from wealthy and patriotic individuals for building wharfs, docks, and storehouses, and for defraying other expenses. These measures of "protection" appear to have been unsuccessful; as were others of various kinds, made in 1677, 1690, and 1720, sometimes through the medium of charters, sometimes through that of Joint-stock companies. Various reasons have been assigned for these repeated failures. Among these reasons may be mentioned, the rule which made London the head-quarters of the fishery (it being the dearest port in the kingdom) and the superiority of the Dutch in the art. Andrew Yarington, in the second part of "England's Improvement by Sea and Land," sums up all other reasons in this one fact—"We fish intolerably dear, and the Dutch exceedingly cheap." In 1749 a committee of the House of Commons was appointed to inquire concerning the herring and white fisheries: and as the result of its labours a corporation was formed, with a capital of 500,000*l.*, under the name of "The Society of the Free British Fishery." A bounty was given to encourage the fishermen, increased in amount from time to time; but this entirely failed in realising the object in view; for, the bounty being given to the vessels and not to the fish, "ships were equipped to catch the bounty and not the herrings." In 1786 "The British Society for extending the Fisheries and improving the Sea Coasts of the Kingdom" was incorporated, and a joint-stock was subscribed "for purchasing land and building thereon free towns, villages, and fishing-stations in the Highlands and Islands of Scotland." This joint-stock was raised by the subscriptions of a few spirited individuals, who did not look for any profitable return. The members of the society were chiefly proprietors of estates, and their object was the improvement of their property. Another act was passed in 1808 for the regulation of the fisheries: granting bounties to the fishermen; and prescribing regulations for fishing, curing, inspecting and branding herrings, and a board of seven commissioners was appointed for administering the law. This act, which was at first passed for a limited time, was made perpetual in 1815. For the inspection and branding of herrings the whole coast of Great Britain was divided into districts. In each of these officers were appointed to oversee the operations of the fishermen, and to prevent frauds in regard to the bounty. The principal regulations affecting the curing of herrings were borrowed from the practice of the Dutch fishermen. In 1817 a further boon was granted to the fishermen by allowing them the use of salt duty free: a peculiar advantage, which ceased in 1823 by the repeal of the duty on that article.

The impolicy of granting bounties on production, the effect of which is to tax the people of this country in order that foreign countries may be supplied with articles of consumption at prices below their actual cost, came at length to be seen and acknowledged. In 1821 the bounty began to be reduced, and in 1830 it ceased altogether. That this alteration of the system has not been productive of any serious evil to the herring-fishery has been abundantly shown by the statistical returns. The average annual number of barrels of herrings cured and exported respectively in the five years that preceded the alteration was 349,488 and 224,370. In the five years from 1826 to 1830, while the bounty was proceeding to its annihilation, the average numbers were 326,896 cured, and 208,944 exported; and in the year 1858, the numbers were 636,122 barrels cured, and 350,204 exported. An end appears to have been put to the protective system by the British Parliament, in the 10 & 11 Vict. c. 91, withdrawing altogether the funds granted year by year for the promotion of the Scotch fisheries; and, in the 21 & 22 Vict. c. 69, exacting a fee for every barrel or half barrel of herrings on which the government brand is imposed, a valuable advantage that had heretofore been conferred on these traders altogether at the public expense. The same act repeals sundry vexatious provisions of previous statutes which had impeded the trade and increased the expense of the traffic without any advantage in return; it prohibits the use of certain nets and certain methods in taking the fish; it prescribes a uniformity in measures; and thus surrenders the traffic to the fostering care of private interest and the salutary effect of public competition.

The Irish fisheries generally continue still to be stimulated by public grants from time to time, without any intention thereby of giving effect to a policy which experience and principle have condemned, but to meet the unfortunate circumstances of that country by furnishing immediate employment to the poor in a traffic more legitimate than the making of public roads that are not wanted, inasmuch as it may become remunerative to the fishermen, and advantageous to the public without the need of extraneous support.

A select committee of the House of Commons was appointed in 1833 to inquire into the state of the British Channel fisheries. A second committee was appointed in 1836 to consider the state of the salmon fisheries in Scotland; and in the previous year commissioners had been instructed to investigate the condition of the Irish fisheries. From each of these bodies reports proceeded which were laid before Parliament, and which contained a considerable amount of information upon the subject. We will present here a few of the leading facts, corrected by the results of inquiries of later date.

The appointment of the committee in 1833 arose out of the distress which was at that time said to affect the several Channel fisheries, and in its report the committee stated that these fisheries were generally in a very depressed and declining state; that they appear to have been gradually sinking since the peace in 1815; that the capital employed did not yield a profitable return; that the number of vessels and of the people to whom it gave employment had diminished; and that the fishermen who formerly could maintain themselves and their families by their industry were in a greater or less degree pauperised. The chief causes of this unfavourable change were considered to be, the interference of the fishermen of France and Holland; and the great and increasing scarcity of all fish which breed in the Channel, compared with what was the ordinary supply 15 to 20 years earlier, operating prejudicially to the fishermen, at the same time that a continued fall of prices had taken place in the markets. The depressed state of the British fisheries is most easily explained by supposing that the foreign fishermen, of whose interference such grievous complaint was made, were better skilled and more persevering in their calling than our own countrymen: a supposition which seems to be borne out by the circumstance of our having, since this report was delivered, been still more abundantly supplied with fish for our tables; while the cry of distress on the part of the fishermen has passed away, doubtless owing to the greater degree of skill and industry which they have since exerted. There was, on the other hand, a complaint preferred against the fishermen by the owners of the boats, who alleged that, having advanced all the capital necessary for the undertaking, and having probably also contributed to the support of the men during the dead season, under the faith of an agreement to receive at stipulated prices all the produce of their nets, the men so bound to them sold a considerable part of the fish which they caught to boats despatched from the coast of France. These circumstances have been mentioned, because a great and it is thought a groundless impression was created by the result of the inquiry of 1833, which inquiry, it has been alleged, was undertaken to satisfy the desires of certain interested parties who wished to make out a case for the interference of government.

These Channel fisheries have been the occasion of much jealousy between England and France, and of continual wrangling between the fishermen of the two countries; they were at length, in 1839, made the subject of a convention between the two governments, and the stipulations contained therein have been embodied into the law of this country successively by the 6 & 7 Vict. c. 79, and the 18 & 19 Vict. c. 101.

Stow-Boat Fishery.—One peculiar branch of fishery is the Stow-boat fishery. This fishery prevails principally upon the Kentish, Norfolk, and Essex coasts; and the object is the catching of sprats, not for food, but as manure for the land, for which there is a constant demand. It fluctuates considerably, according to the price of other agricultural manures, and to the abundance of the shoals of fish.

Pilchard Fishery.—The pilchard fishery, which is carried on upon parts of the Devon and Cornish coasts, is of some importance. The pilchards visit our shores in August and September, and again in November or December: they come in large shoals into shallow water. As soon as caught they are salted or pickled and exported to foreign markets, chiefly to the Mediterranean: the average export amounts to 30,000 hogsheads per year.

Herring Fishery.—The extent of the British herring-fishery has already been noticed. The places where it is principally carried on are Yarmouth, Lowestoft, Hastings, Folkestone, Cardigan Bay, and Swansea, in England and Wales; the coasts of Caithness, Sutherland, Aberdeenshire, Banffshire, Morayshire, and Ross-shire, in Scotland; and Galway, Killybegs on the coast of Donegal, Mayo, the æstuary of the Shannon, the coast between Dingle Bay and Kenmare, Bantry Bay, Waterford, and from Mizen-head to Cahore point on the Wicklow coast, in Ireland. The principal herring-fishery off the coast of Norfolk and Suffolk commences in September and ends in the beginning of December. Mackerel fishing begins 1st May, and ends 1st July. No material changes have occurred in the seasons, but herrings are more numerous of late years on the Yorkshire coast.

Salmon Fishery.—Our chief salmon-fisheries are carried on in the rivers and æstuaries of Scotland. As no bounty has been at any time payable upon the taking or exporting of this kind of fish, there are no means of ascertaining its actual or comparative amount. Great interest and activity have in recent years been evinced by noblemen and the landed gentry, with much success, in promoting the breed of salmon, and the protection thereof has long been an object with the British Parliament, who by various Acts, 1 Geo. I. c. 18; 58 Geo. III. c. 43; 6 & 7 Vict. c. 33; and 11 & 12 Vict. c. 52, have prescribed certain regulations, and prohibited the taking of fish at certain periods of the year, with the same end in view. The produce of the fishings in the rivers Dee, Don, Spey, Findhorn, Beauly, Borriedale, Langwell and Thurso, and of the coasts adjacent, are conveyed in steam-boats and small sailing vessels to Aberdeen, where they are packed with ice in boxes and sent to the London market, either by steamers or by railway. The most productive salmon-fisheries in Ireland are situated near the mouths of the rivers, on nearly all parts of the coast.

Mackerel Fishery.—Mackerel are fish of passage which visit every part of our coasts in the spring and early part of the summer, and are taken in great abundance. In this country they are used fresh, and great quantities are conveyed by rapid railway journeys from the coast to London. The general desire to obtain this fish in perfection has led to the well-known relaxation of our laws against Sunday trading, which permits the open hawking about of mackerel on that day: a practice which is punishable with regard to any other fish, or indeed to articles of any kind, with the exception of milk.

The principal fisheries on the eastern coast of England are in the neighbourhood of Whitby, Hartlepool, and Robin Hood's Bay. The fish-markets of the great towns in the interior are now supplied more abundantly than ever with fish, through the agency of railways.

Cod Fishery.—The cod fishery at Newfoundland was carried on as early as 1500 by the Portuguese, Biscayans, and French; but it was not until 1585 that the English ventured to interfere with them. In that year Sir Francis Drake, being sent to the island with a squadron, seized the foreign ships which he found engaged in the fishery, and sent them to England, where they were declared lawful prizes. In 1610 a company was incorporated for the same purpose by King James I., and so successfully was the fishery prosecuted, that in 1614 there were near 200 vessels engaged in it; in the following year the number exceeded 250. The English fishermen were, however, closely pressed by those of France, who had sundry advantages in their favour. By the treaty of Utrecht, which acknowledged the sovereignty of the whole island of Newfoundland to be in the crown of England, the privilege of fishing on part of the coast was reserved to France, notwithstanding which the English fishery there increased to a great extent. The resort of the United States fishermen to the coasts of Newfoundland for the purpose of sharing in this remunerative traffic began early to excite the jealousy of the British fishermen, and the quarrels arising in consequence appealed so strongly to the peculiar sympathies and pride of the respective countries, that armed vessels were sent to the fishing-ground, nominally to preserve peace and order, and serious apprehensions were created as to the possibility of maintaining the peaceful relations between the two governments. At length a treaty was concluded in 1854 between England and the United States, and the stipulations of it became the law of this country by the 18 & 19 Vict. c. 3. By this treaty, the right of taking all kind of fish except shell-fish, and curing and drying fish, is granted to the fishermen of the United States on the sea-coasts, shores, bays, and harbours of Canada, New Brunswick, Nova Scotia, Prince Edward's Island, and with some modification, Newfoundland. The principal fisheries of Newfoundland are prosecuted on the banks which nearly surround that island; the object of these fisheries is solely cod-fish. Salmon, mackerel, herrings, and some other kinds of fish are taken off the coasts of the island; and the seal fishery is carried on successfully, yielding a considerable number of seal-skins and a large quantity of seal-oil for exportation. These fisheries may be said to be the sole pursuit of the settlers in Newfoundland, and of the traders who frequent the island. Nearly every family has a small piece of land under garden cultivation, but agriculture is not pursued as a substantive occupation.

Whale Fishery.—The whale fishery was carried on successfully during the 12th, 13th, and 14th centuries, by the Biscayans. The whales taken by them in the Bay of Biscay appear to have been of a smaller species than those since found in more northern latitudes. The Biscayan fishery has long ceased, owing probably to the great destruction of the animals. It is to the voyagers who, near the end of the 16th century, attempted to find a passage through the northern ocean to India, that we owe the discovery which led to the establishment of the fishery in the seas of Greenland and Spitzbergen. The English and the Dutch were the first to embark in this adventure; but the French, Danes, Hamburghers, and others were not slow to follow their example. At first the whales were so numerous that the fishing was comparatively easy, and was so successfully pursued that, in addition to the ships actually engaged in the fishery, many other vessels were sent in ballast to the shores of Spitzbergen, and the whole returned home with full cargoes of oil and whalebone. It was then the practice to boil the blubber on the spot, and bring home the oil in casks. In the progress of the fishery the whales became less numerous, and, when found, more difficult to take. It therefore became necessary to pursue them farther to the open sea, and at length it was found more economical to bring the blubber home in order to its being boiled, and the settlements before used for that purpose were abandoned. That part of the Arctic Sea which lies between Spitzbergen and Greenland, and which was formerly frequented by the whale ships, is now almost wholly abandoned because of the scarcity of the fish, and the northern whale fishery is now chiefly pursued in Davis's Straits. Previous to the revolt of the North American provinces this fishery, as well as that in the Southern Ocean, was prosecuted with great spirit by the colonists of Massachusetts. Just before the beginning of the war they employed annually 183 ships of 13,820 tons in the Northern, and 121 ships of 14,026 tons in the Southern whale fisheries.

It was not until after the breaking out of war between England and the American provinces had, for a time at least, interrupted this spirit of enterprise, that England embarked in the Southern fishery. Towards the close of the last century, the number of English vessels so employed was considerable; in 1791 they amounted to 75, but the number has since greatly fluctuated. It requires a considerable sum of money to fit out a ship. A new vessel of the size usually employed —350 tons—costs, when ready for sea and fully provisioned, from 12,000*l.* to 15,000*l.*; and the adventurer must wait three years for the return of his capital.

FISTULA LACRYMALIS. [Lacrymal Organs, Diseases of.]

FIT. [Syncope.]

FIXED AIR. [Carbonic Acid.]

FIXED OILS. The fixed oils constitute an important division of that well-known group of natural substances generically termed fatty matters. The name oil sufficiently indicates the liquid character of the members of this division; and they are said to be *fixed*, because they may be heated to nearly 500° Fahr. without undergoing material change, that degree of heat being far above the temperature necessary for the perfect volatilisation of any of the *essential oils*—another division of the fatty group. [Essential Oils.]

Source. Fixed oils are mainly obtained from the vegetable kingdom, residing for the most part in the seed, but occasionally in the fruit of plants. Certain cold-blooded animals, notably the cod-fish, and several cetaceans, such as the sperm whale, also furnish fixed oils of considerable economic value. [Oils, in Nat. Hist. Div.]

Preparation. The most usual method of obtaining a fixed oil is by submitting the substance from which it is to be extracted to strong pressure. For this purpose hydraulic presses are very generally employed. Heat is occasionally made use of to increase the liquidity of the oil, the plates of the press being kept hot for this purpose, and the substance itself usually previously exposed in bags to the action of steam. Oil obtained in this way may be rendered quite bright and transparent, either by subsidence, or filtration through paper or flannel. Another process for obtaining fixed oil consists simply in boiling the substance with water, when the oil rises to the surface and may be skimmed off. A useful laboratory method of extraction is digestion of the substance in alcohol or ether, or a mixture of the two, and subsequent separation of the solvent by heat.

Purification. But few oils are at once obtained from their natural source in a state fit for use, and no generally applicable process can be named by which they may be refined and bleached. Exposure to light in glass bottles is sufficient to decolorise many of them. Digestion with strong sulphuric acid for a time, and subsequent treatment either with cold water, or if necessary with steam, or simply blowing steam through the oil without the addition of sulphuric acid, are other methods of purification. Tannic acid, under the form of a strong decoction of oak bark, is occasionally employed to separate albuminous and gelatinous matter. Caustic soda, in small quantity, with the aid of heat, will generally separate sulphur contained in an oil, and improve its appearance and odour. Chromic acid is perhaps the most energetic oil-bleaching agent. It is conveniently applied by adding to the oil a saturated solution of bichromate of potash containing nearly half its weight of strong sulphuric acid. The *rancidity* of oils may be removed by washing with cold water alone, or with a very dilute aqueous alkaline solution.

Properties. The fixity of the bodies under consideration is obviously their great characteristic. Their specific gravity is always less than that of water, ranging from 0·90 to 0·93. Their consistence varies; heat renders them more liquid, cold congeals or solidifies them. When perfectly pure they have little or no smell, but as usually met with possess more or less characteristic odours, due to the presence of such volatile matters as butyric, valeric, or caproic acid, &c. When these matters are present in excess, oils are said to be rancid.

The fixed oils are insoluble in water, and, with the exception of castor oil, almost insoluble in alcohol; they however readily dissolve in ether, benzole, and oil of turpentine, and are miscible in all proportions with each other and with the essential oils. When heated in close vessels to 500° or 600° Fahr. they are decomposed, irritating vapours are evolved, and permanently gaseous bodies, as well as some liquid and solid substances, are produced. These products are all inflammable, burning with a luminous flame; indeed an ordinary oil-lamp is a miniature apparatus for the combustion of the products of the destructive distillation of oil. [Candle Manufacture.]

In chemical composition the fixed oils greatly resemble each other. They contain Fatty Acids, in slightly variable proportions, united with glycerin: the oleate of glycerin, however, preponderating. Ammonia acts upon fixed oils, converting them into amides; but the other caustic alkalies, and some metallic oxides, form with them true soaps. All fixed oils are more or less acted upon when exposed to the air. Some slightly thicken and acquire rancidity, but do not become solid; others rapidly absorb oxygen, give out heat, and ultimately dry up into a kind of resin. When the latter kind of oils are exposed to the air in a finely divided state, such as occurs when paper, cotton, shavings, straw, &c., are saturated with them, this oxidising action goes on at such a rate that the heat evolved is sufficient to cause the inflammation of the mass. [Combustion, *Spontaneous.*]

Drying and non-drying oils. From what has just been stated, it is evident that fixed oils may be divided into these two classes. The principal *drying oils* are those of linseed, poppy, sperm, walnut, cod-liver and hemp. They are largely used in the preparation of varnishes and by the painter as vehicles for pigments. Their drying property is considerably increased by heating them with litharge (oxide of lead) or with oxide of manganese; they are then technically termed *boiled oils.* The chief *non-drying oils* are those of almond, colza, olive, rape, as well as all that are of animal origin: they are further distinguished from the drying oils by being converted into the solid state by mercurous nitrate or by $\frac{1}{200}$th part of their weight of peroxide of nitrogen (NO_4), and are used in cookery, for lubricating machinery, and for burning in lamps.

Tests for purity. General tests for the purity of fixed oils are smell, taste, and specific gravity. Special tests for the principal of them will be found described under their respective names. The action of sulphuric acid is also a valuable aid in individualising the fixed oils; a table of the action of, and details concerning, this reagent will be found in 'Cooley's Cyclopædia of Practical Receipts,' article 'Oils.'

Another systematic method, by Calvert, is described in 'Muspratt's Chemistry' as applied to the arts and manufactures, article 'Oil.'

Alphabetical list of the chief fixed oils.

Almond oil. [Amygdalus.] A non-drying oil.

Appleseed oil. Obtained by expression from apple-pips. It resembles poppy oil.

Bay oil. Non-drying. [Laurus Nobilis in Nat. Hist. Div.]

Beech oil. Non-drying. Sp. gr. 0·9225. [Beech. Fagus in Nat. Hist. Div.]

Belladonna oil. From the fruit of *Atropa Belladonna.* Sp. gr. 0·925: a drying oil.

Ben oil. [Ben, oil of.] Non-drying.

Cacao oil. [Cacao.] Non-drying.

Camelina oil. From the seed. [Camelina Sativa in Nat. Hist. Div.] Drying. Sp. gr. 0·9252.

Carapa oil. From the fruit. [Carapa in Nat. Hist. Div.]

Castor oil. Obtained by expression from the seeds of *Ricinus Communis.* Sp. gr. 0·969. Dries by very long exposure. Its nauseous taste is said to be removed by agitation with magnesia. Is miscible with alcohol. Contains a modification of oleic acid termed *ricinoleic acid.* Heated with caustic potash, sebacic acid is produced, hydrogen is evolved, and caprylic alcohol distils over.

Cebadilla oil. From the seed. [Cebadilla in Nat. Hist. Div.]

Cherry-stone oil. From the kernel. Sp. gr. 0·9239.

Chestnut oil. From horse-chestnuts. Non-drying. Sp. gr. 0·927.

Cocoa-nut oil. Non-drying. Solid at common temperatures. [Cocos, in Nat. Hist. Div.]

Cod-liver oil. From the liver of the common cod-fish. [Morrhua *vulgaris* in Nat. Hist. Div.] To obtain a pure pale yellow oil for medicinal purposes, the livers, after washing with cold water, are submitted to gentle heat in steam-jacket pans for about three quarters of an hour; on cooling, the oil separates and floats on the surface, is skimmed off and clarified by subsidence in deep cisterns and by filtration, first through flannel, and finally through moleskin under pressure. It is exported from Newfoundland in casks, one manufacturer alone producing between 20,000 and 30,000 gallons annually.

Other cod-liver oils occur in commerce; they are all of a more or less brown colour, and are obtained from the livers after exposure to the sun. The livers undergo putrefactive fermentation, and yield a larger per centage of oil than when treated as already described for the medicinal oil. The livers of other fish than the cod are also used in the manufacture of common cod oil. It is principally used by curriers for dressing leather.

Colza oil. Non-drying. [COLZA, OIL OF.]

Cornelberry oil. Non-drying. From the fruit. [CORNUS *sanguinea*, in NAT. HIST. DIV.]

Cotton-seed oil. From the seeds of one of the cotton plants. [GOSSYPIUM *barbadense*, in NAT. HIST. DIV.] This oil dries on exposure to the air.

Cress oil. From the seeds of common garden cress (*Lepidium sativum*). Sp. gr. 0·924. Drying.

Croton oil. [CROTON OIL.]

Cucumber oil. From the seeds of several species of *Cucumis* and *cucurbita*. Drying. Used for lamps. Sp. gr. 0·9231. Known also as *Gourd oil.*

Cyper-grass oil. One of the very few oils obtained from the *root* of a plant (*Cyperus esculenta*). Non-drying. Sp. gr. 0·918.

Garden-spurge oil. [EUPHORBIA *lathyris*, in NAT. HIST. DIV.]

Gingelly oil. From the seeds of *Sesamum orientale.* Also known as *Teel oil*, *Benne oil*, and *Oil of sesamum.* It is non-drying.

Gourd oil. See *Cucumber oil.*

Grapeseed oil. By expression from the seeds of grapes. Used in salads and for burning. Sp. gr. 0·9202. Also known as *Oil of winestones.* It dries on exposure.

Ground-nut oil. Non-drying. [ARACHIS *hypogæa*, in NAT. HIST. DIV.]

Hemp oil. From the seeds of common hemp. [CANNABIS *sativa*, in NAT. HIST. DIV.] Soluble in alcohol. Sp. gr. 0·9276.

Henbane-seed oil. Non-drying. Sp. gr. 0·913. [HYOSCYAMUS, in NAT. HIST. DIV.]

Indayaçu oil, From the seeds of *Anda Gomesii.* Properties similar to those of castor oil.

Jatropha oil. [JATROPHA *curcas*, in NAT. HIST. DIV.]

Julienne oil. Drying. Sp. gr. 0·9281. From the seeds of Dame's violet. [HESPERIS *matronalis*, in NAT. HIST. DIV.]

Kundah oil. [CARAPA, in NAT. HIST. DIV.]

Lard oil. Crude oleic acid. A secondary product in the manufacture of stearin, or obtained from lard by boiling with alcohol. Sp. gr. 0·9003.

Laurel oil. See *Bay oil.*

Linseed oil. [LINSEED OIL.]

Mace oil. See *Nutmeg oil.*

Madia oil. [MADIA, in NAT. HIST. DIV.]

Mustard oil. The seeds of the white mustard (*Sinapis alba*), yield from thirty to forty per cent. of an oil used in salads. Many other species of sinapis yield a similar oil. That from black mustard is used externally as a stimulant. The seeds of wild mustard (*Raphanus raphanistrum*) also yield a fixed oil.

Neat's-foot oil. Floats on the surface of the water in which neat's feet are boiled. It is used for lubrication and for softening leather.

Nettle-tree oil. From the kernels of the *Nettle-tree* (*Celtis australis*). Used for burning.

Nickar oil. From nickar nuts, the kernels of *Guilandina bonducella.*

Nut oil. The kernels of the common hazel nuts [CORYLUS *avellana*, in NAT. HIST. DIV.] contain more than half their weight of an excellent drying oil. Sp. gr. 0·926.

Nutmeg oil. The so-called *expressed oil of mace*, is a mixture of the essential and fixed oils of the nutmeg. It is obtained on pressing the bruised nutmegs between hot plates. [MYRISTICA, in NAT. HIST. DIV.]

Olive oil. [OLIVE OIL; OLEA *europæa*, in NAT. HIST. DIV.]

Palm oil. Solid. Largely used in soap and candle manufacture. Sp. gr. 0·968. [ELÆIS, in NAT. HIST. DIV.]

Palma-Christi oil. See *Castor oil.*

Pine-nut oil. From the seeds. [PINUS *pinea*, in NAT. HIST. DIV.]

Pine top oil. From the Norway spruce fir. Dries on exposure. Sp. gr. 0·9285.

Piney oil, pœno tallow. [VATERIA, in NAT. HIST. DIV.]

Pistachio nut oil. From the kernels. [PISTACIA *vera*, in NAT. HIST. DIV.]

Plumstone oil. The kernels of the common plum (*Prunus domestica*) contain thirty per cent. of a lamp oil. Sp. gr. 0·9127. Non-drying.

Poppy oil. The seeds of the common white poppy contain half their weight of fixed oils. It dries well, and is much used in the manufacture of paints and soaps, also in salads, and to adulterate almond oil. Sp. gr. 0·9244. [PAPAVER *somniferum*, in NAT. HIST. DIV.]

Prune-stone oil. The kernels of the common prune contain an oil resembling that of almonds, but it rapidly becomes rancid. Sp. gr. 0·9127.

Radish seed oil. From the seeds of a variety of the common radish. Non-drying. Sp. gr. 0·9187.

Rape oil. From the seeds of *rape* (*Brassica compestris*). When refined by treating with sulphuric acid, it is used for common purposes in the place of olive oil.

Sabadilla oil. See *Cebadilla oil.*

Sassafras-nut oil. From the kernels. [NECTANDRA *puchury minor*, in NAT. HIST. DIV.]

Seal oil. Obtained from the blubber of several species of seal [PHOCIDÆ, in NAT. HIST. DIV.], the portion that first drains away being palest in colour and most valuable. Used for burning and leather dressing.

Sesamum oil. See *Gingelly oil.*

Shark-liver oil. From the livers of several species of *Squalidæ*. It is the lightest of all the fixed oils, having a sp. gr. of 0·866.

Skate oil. From the livers of various skates (*Raiania*). It resembles cod-liver oil.

Sperm oil. A valuable oil for lamps, and for lubricating machinery. It is the liquid portion of the fatty matter found in various parts of the White or Sperm whale (*Physeter macrocephalus*), the solid portion being spermaceti. [SPERMACETI, in NAT. HIST. DIV.]

Sunflower oil. From the seeds of the common sunflower. Used for burning, and in salads. Sp. gr. 0·9261.

Teel oil. See *Gingelly oil.*

Tobacco-seed oil. A good drying oil, obtained from the seeds of the tobacco plant (*Nicotiana tabacum*). Sp. gr. 0·9232.

Touloucouna oil. [CARAPA, in NAT. HIST. DIV.]

Train oil. See *Whale oil.*

Walnut oil. The kernels of walnuts contain half their weight of a fixed oil, sometimes used in mixing up colours for house-painting.

Weld oil. From the seed of *dyer's woad* (*Reseda luteola*). It dries on exposure. Sp. gr. 0·9358.

Whale oil. From the blubber of the common or Greenland Whale. It somewhat resembles sperm oil, but is darker in colour and of disagreeable odour. It is used as a lubricating agent, and is occasionally burnt in lamps. Sp. gr. 0·927.

Wine-stone oil. See *Grapeseed oil.*

FIXTURES. The term "fixtures" is frequently used to signify articles of a personal nature which have been affixed to land, whether removeable or not, and sometimes expressly to denote articles which are not by law removeable when once attached to the freehold: but the term "fixtures," in its correct legal sense, signifies such things of a personal nature as have been annexed to the realty, and which may be afterwards severed or removed by the party who annexed them, or his personal representatives, against the will of the owner of the freehold. When the article is not so removeable, it is to all intents and purposes part of the freehold, and subject to the rules and incidents of real property.

It is necessary, in order to constitute a fixture, that the article should be let into or united with the land, or to other substances previously connected therewith. Goods, and even buildings of the most ponderous description, do not fall under the description of fixtures, if they are merely laid and rest upon the earth without being let into it. Something more than mere juxta-position is required, as, for instance, that the soil shall have been displaced for the purpose of receiving the article, or that the chattel shall have been connected or otherwise fastened to some fabric previously attached to the ground.

The old rule of law was, that whatever was once fixed to the land was thereby made a part of it, so as to be irremoveable by any one but the owner of the fee-simple. But the strictness of this rule has been from time to time considerably relaxed, regard being had to the object of the annexation, the nature of the article, the relation of the parties between whom questions have arisen, and other considerations. Questions as to fixtures arise principally between three classes of persons. 1st, Between landlord and tenant; 2ndly, Between the executors of a tenant for life or in tail and the remainder-man or reversioner; and, 3rdly, Between the heir and the executor of the party who put up or attached the article to the premises.

1. As to the law of fixtures between landlord and tenant.

A tenant may in general remove articles which he has himself affixed to the premises solely for the purpose of trade and manufactures, wherever the removal is not contrary to any prevailing custom of trade. It cannot however be said to be established that a tenant may remove substantial and permanent additions to his premises on the ground of their having been built exclusively for the purposes of his trade, such as workshops, storehouses, mills, or other buildings of that description; nor is it clear that trade-erections of a less substantial character, such as furnaces and flues of smelting or glass-houses, or the stories and floors of malting-houses, &c., are in all cases removeable by a tenant. In such cases, somewhat will depend upon the degree in which the freehold will be deteriorated by the removal of the article, or the article itself injured or destroyed before it can be taken away.

There are also instances in which articles which have been fixed to the freehold, partly for the purposes of trade and partly for other purposes, have been held removeable. Besides the above, many fixtures slightly put up for the ornament of a house or for domestic use may also be removed by the tenant. But things attached to the freehold for agricultural purposes only are not removeable.

The following lists, given by Chitty, in his treatise on the 'Law of Contracts' (6th edit.), show what fixtures have been decided or considered, according to judicial dicta, to be removeable or not as between landlord and tenant.

1. List of things held not to be Removeable by the Tenant:—

Agricultural erections.
Alehouse bar.
Barns fixed in the ground.
Beast-house.
Benches.
Box-borders.
Carpenter's shop.
Cart-house.
Chimney-pieces (in general).
Conservatories.
Doors.
Dressers.

- Flowers.
- Foldyard walls.
- Fruit trees.
- Fuel-house.
- Glass windows.
- Hearth.
- Hedges.
- Improvements, permanent.
- Jibs.
- Keys.
- Locks.
- Millstones.
- Partitions.
- Pigeon-house.
- Pineries substantially fixed.
- Pump-house.
- Racks in stables.
- Strawberry beds.
- Trees.
- Waggon-house.
- Windows.

2. List of things held to be Removeable by the Tenant (though not Trade Fixtures):—

- Arras hangings.
- Barn set on blocks, &c.
- Beds fastened to ceiling.
- Bells.
- Bins.
- Blinds.
- Book-cases.
- Buildings set on blocks.
- Rollers, pillars, &c.
- Cabinets.
- Chimney backs.
- Chimney-glasses.
- Chimney-pieces (ornamental).
- Cider mills.
- Cisterns.
- Clock-cases.
- Coffee-mills.
- Cooling coppers.
- Coppers.
- Cornices (ornamental).
- Cupboards.
- Dutch barns.
- Furnaces.
- Furniture, fixtures put up as.
- Granary on pillars.
- Grates.
- Hangings.
- Iron backs to chimneys.
- Iron chests.
- Iron malt-mills.
- Iron ovens.
- Jacks.
- Lamps.
- Looking-glasses.
- Malt-mills.
- Marble chimney-pieces.
- Marble slabs.
- Mash-tubs.
- Mills on posts.
- Mills laid on brick foundations.
- Ornamental fixtures.
- Ovens.
- Pattens, erections on.
- Pier-glasses.
- Posts.
- Presses.
- Pumps slightly attached.
- Rails.
- Ranges.
- Sheds.
- Shelves.
- Sinks.
- Slabs of marble.
- Stable on rollers.
- Stoves.
- Tapestry.
- Tubs.
- Turret clocks.
- Vessels, &c., on brickwork.
- Wainscot, fixed by screws.
- Water-tubs.
- Windmill on posts.

3. List of Trade Fixtures decided or said to be Removeable by the Tenant:—

- Accessary buildings, that is, accessary to a removeable utensil.
- Brewing vessels and pipes.
- Cider-mills.
- Cisterns.
- Closets.
- Colliery machines.
- Coppers.
- Counters.
- Cranes.
- Desks.
- Drawers.
- Dutch barns.
- Engines.
- Fire engines.
- Fruit trees planted by nurserymen.
- Furnaces.
- Gas pipes.
- Glass fronts.
- Iron safes.
- Machinery, let into caps or steps of timber, or fixed with screws to the floor or to sockets of lead let into the stonework of the building.
- Partitions.
- Plants and pipes of brewers, distillers, &c.
- Presses.
- Pumps.
- Reservoirs.
- Salt-pans.
- Shelves.
- Shrubs planted for sale.
- Soap works, fixtures in.
- Steam-engines.
- Stills.
- Trees planted for sale.
- Varnish-house.
- Vats.

There are also certain fixtures as to which the right of removal is unsettled, but has been the subject of discussion, in determining some of the cases already referred to; of the doubtful articles the subjoined is a list:—

- Brick-kilns.
- Frames in nursery grounds.
- Furnaces in smelting-houses and glass-houses.
- Glasses in nursery-grounds.
- Green-houses.
- Hot houses.
- Lime-kilns.
- Malting-floors, stoves, &c.
- Pavements.
- Sheds.
- Storehouses.
- Tables, fixed or dormant.
- Verandahs.
- Wind or water mills.
- Workshops.

It must not however be assumed that no circumstances can except the enumerated articles from the decisions respecting them. The peculiar circumstances of each case, the state or position of the fixtures in question, and the consideration of the degree of injury to be caused by their removal, are so much regarded by the courts that few decisions can be regarded as absolute authorities for other cases, even with respect to fixtures of a similar description.

The general rule is, that a tenant must remove his fixtures before the expiration of his tenancy, or during such time as he continues in possession under a right to consider himself as tenant, for he is not at liberty to insist on his claim afterwards. And if the interest of the tenant is of uncertain character, as of a tenant strictly at will, or *pur autre vie*, it is the common opinion that he will be entitled to a reasonable time after the determination of his tenancy to remove his fixtures.

The rights both of landlord and tenant with respect to fixtures are frequently modified and controlled by the terms of the demise, according to the general principle that parties may, by entering into a special contract, vary their legal rights with respect to each other. Thus, a covenant by the tenant to keep in repair all erections and buildings erected and built, "and thereafter to be erected and built," and to surrender them at the end of the term, will preclude him from removing erections put up by himself, and which, but for the covenant, might have been legally removed as trade fixtures. And therefore a tenant, before severing an article from the freehold, must consider his right not only under the general law of fixtures, but as it may be affected by an express or implied covenant in his lease.

It should be observed, that any erection or building, whatever be its purpose, and however substantial it be in itself, unless it be affixed to the freehold according to the definition of a fixture before given, will not belong to the landlord at the end of the term. Thus, if the tenant erect a barn, granary, stable, or other building upon blocks, rollers, pillars, or the like, the landlord will not be entitled to it as part of his freehold. The tenant may therefore, by adopting appropriate modes of construction, make many valuable additions to his premises without losing his property in them, and at the same time avoid the effect of a covenant to repair erections which are put up by him during the term.

2. As to the law of fixtures between tenants for life or in tail, or their personal representatives, and the remainder-man or reversioner.

There are only few cases in which the claims of tenants for life or in tail to fixtures have come before the courts; but it appears generally from the authorities, that fixtures set up either wholly or partially for the purposes of trade form part of the personal estate of a tenant for life or in tail, and are excepted out of the general rule in favour of the inheritance; and it may be inferred from the analogy of decisions in cases between heir and executor, that the exception will extend to certain articles put up for ornament or convenience, provided they are not united to the freehold by any permanent or substantial mode of annexation.

It is necessary to distinguish between the rights of tenants for life and in tail under the law of fixtures from those which they possess under the general principles of tenure as incident to their estates. A tenant in tail, by reason of the nature of his estate, may, independently of the law of fixtures, remove any thing he has affixed to the premises. A tenant for life, again, is not in general entitled to commit any kind of waste; but if he holds his estate *without impeachment of waste*, he possesses powers arising out of his estate similar to those of the tenant in tail. [WASTE.] But in either case those powers must be exercised during the life of the tenant, as they cease at his death, and nothing survives to his representative except his right under the law of fixtures.

Ecclesiastical persons are considerered as tenants for life of their benefices, and the rights of such persons or their representatives with respect to annexations made by them to the freehold resemble very nearly those of other tenants for life.

3. As to the law of fixtures between heir and executor.

There appears to be more uncertainty in the doctrine of fixtures as between the heir and the executor, than between any other class of persons. In the early periods of the law, the rule that whatever was affixed to the freehold should descend to the heir as parcel of his inheritance, was rigidly adhered to, and even in later times the decisions and dicta of the judges upon the subject are by no means easy to reconcile. It may however be inferred from them generally, that as between the heir and executor trade fixtures and fixtures erected partly for trade and partly for other purposes, are part of the personal estate. This will be the case when the fixtures have been put up for the purposes of a trade which is merely personal, and has no connection with the land, and even in some cases, as that of Cider-mills (see 3 Atk. 14), where the trade is connected with the profits of the land; but if the property in question is absolutely essential to the value and enjoyment of the land, as was decided with respect to Salt-pans (1 H. Bl., 260, *n.*), it cannot be removed by the executor, but will descend to the heir as part of the inheritance. There are some articles put up for ornament or domestic use to which the executor has been held entitled, such as pictures, mirrors, hangings, cornices, &c., where the degree of annexation is slight, and the freehold will not be much deteriorated by the removal.

In questions with respect to fixtures, whether between landlord and tenant, tenant for life or in tail and the person entitled in remainder or reversion, or between heir and executor, much will frequently depend, not only upon the nature of the article, but also upon its construction, and the mode of its annexation to the freehold. The rule as to severance is construed most liberally in favour of the tenant as against the landlord, not quite so strongly in favour of the tenant for life or in tail, as against the remainder-man or reversioner, and in favour of the heir rather than that of the executor. This must always be remembered in drawing inferences from decisions between different parties. Thus a decision in favour of the executor against the heir may be relied on between whatever parties the question may arise, but decisions in favour of the tenant against the landlord cannot be relied upon as conclusive in cases between other parties.

With respect to the transfer of fixtures the general rule is, that a conveyance or mortgage in general terms of lands and houses includes personal chattels attached thereto, though such chattels might otherwise have been removed under the law of fixtures. When the conveyance is not general, but contains a stipulation that "the fixtures are to be taken at a valuation," the question what fixtures are included (in the absence of a schedule or specification) is to be determined by the relative situation in which the parties are placed by the conveyance. If the conveyance be an absolute sale, then those articles only should be valued which would be fixtures as between heir and executor; if there be a demise only, or the assignment of a lease, the valuation should extend to all that would be considered tenant's fixtures as between landlord and tenant. If the description of the premises in the renewal of a lease contain the general terms, "lands, buildings, erections," &c., fixtures are considered to be included in the demise, and the tenant cannot afterwards remove them, whatever were his rights before the new lease was granted.

It is now settled that contracts exclusively for the sale of fixtures are valid without the formalities prescribed by the 4th section of the Statute of Frauds (29 Car. II. c. 3); though if the slightest interest in the realty be intended to pass, the statute will apply. It would seem too, that a contract for the sale of fixtures is not within the 17th section of the statute as a contract for the sale of goods and chattels.

(See the Treatise of Messrs. Amos and Ferard on the *Law of Fixtures;* and Chitty, *On Contracts*, 6th ed.)

FLAG, the ensign or colours of a ship hoisted to denote nationality, or as a signal. The word is usually supposed to have been derived from the Anglo-Saxon *fleogan*, to fly or float in the wind; but the motion of a flag in the air being similar to the flickering of a flame, the origin of the word may probably be in the very old Latin root "flag," to flare or blaze.

The supreme flag of Great Britain is the royal standard, which is only to be hoisted when the sovereign or one of the royal family is present; the second is that of the anchor on a red field, which characterises the lord high admiral, or lords commissioners of the Admiralty; and the third is the union flag, in which the crosses of St. George, St. Andrew, and St. Patrick are blended. This flag is appropriated to the admiral of the fleet, who is the first naval officer under the lord high admiral. The British ensign is red with the union jack borne as a *canton*. The Customs department is distinguished by its having a crown in the *field* as a *bearing*.

In the British navy a fleet is divided into three squadrons—the centre, the van, and the rear; the centre being distinguished by red ensigns, the van by white, and the rear by blue, and respectively commanded by an admiral, a vice-admiral, and a rear-admiral. When the fleet is very large, there are three divisions in each squadron; and each squadron has then its admiral, vice-admiral, and rear-admiral, who respectively hold the command of its centre, van, and rear divisions. The admirals are divided in like manner, there being an admiral, a vice-admiral, and a rear-admiral of the red squadron, and so of the white and blue squadrons; but in all cases an admiral carries his flag at the main, the vice-admiral at the fore, and the rear admiral at the mizen.

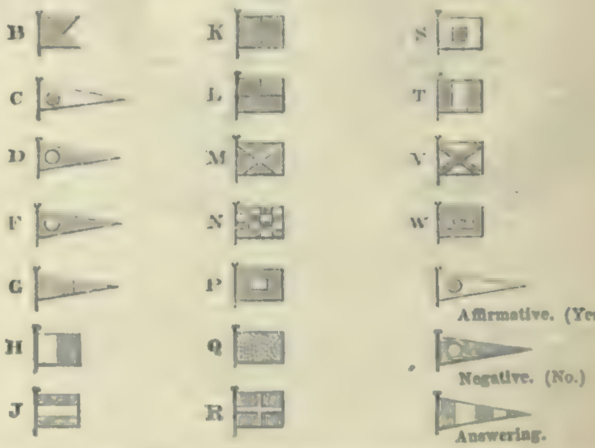
The three flags are plain red, white bearing the red cross of St. George, and plain blue; and the ensign worn by the ship that carries a flag, as well as by every ship belonging to the same squadron, is always of the same colour as that of the flag-officer commanding it. Various kinds of flags are used in addition, to convey orders, to ask assistance, to announce arrivals, &c.; and a regular system of communication can be readily maintained between fleets or ships at sea.

In the British merchant service, which contains nearly 40,000 registered vessels, increasing in number about 1500 in new vessels annually, the want of a more simple communication by signal became so pressing that in 1855 a committee was appointed by the Board of Trade to consider the subject. Marryatt's excellent code had been used for nearly half a century, and, from the difficulty which affects all radical changes in public systems, years will pass before it is wholly discontinued. It has, however, been determined by the committee that signals for the merchant service ought to extend to at least 70,000 or 80,000 in number; and that no signal should have more than 4 flags in a hoist. Steamers have in general much shorter masts than sailing vessels, and therefore the higher numbers of Marryatt's Code requiring 5 flags, has been pronounced a solid objection thereto.

After considerable attention to the subject by the committee, composed of highly competent members, it has been resolved that a new system containing 18 flags and 3 pendants, which would furnish 78,642 signals, each consisting of not more than 4 flags in a hoist, be adopted in the merchant navy of Great Britain. This so desirable a change, effected by the substitution of *letters* for numbers (omitting the vowels) gives to the merchant marine, not only a comprehensive and simple code capable of extension, but furnishes an authorised base on which to found an *Universal System*, which other nations will doubtless approve and apply.

From the rapidly increasing interest which attaches to nautical matters in this country, we subjoin a list of flags under this new system:—

N.B. Blue is represented by lines, thus ▤
Red " " ▥
White " absence of all lines
Yellow " lines, thus ▨



The following are the names of the varieties of flags in the sea service, the ordinary square flag being the one most in use. It has of late years become a custom for shipowners each to adopt a private, or as it is called, a "House Flag."

Mast-head pendant.

FLAGELLANTS, FLAGELLATION. The idea of propitiating the Deity by self-torment dates from a remote antiquity. Herodotus relates (ii. 42) that the Egyptians flogged themselves at one of their annual celebrations. Flagellation was administered as a trial of fortitude to the young Lacedæmonians, who it seems, in accordance with the peculiar institutions of Lycurgus, did not attach to this castigation the idea of degradation which modern Europeans do. In Rome, however, the punishment of flagellation was only applied to slaves, and it seems to have been pretty common, as different classes of slaves derived their names from the kind of whips with which they were lashed. Some were called *Restiones*, because they were lashed only with cords; others *Buccdæ*, from being flogged with thongs of ox-leather. It is in reference to this custom that Plautus makes one of his personages say—"*Erunt Buccdæ inviti potius quam ego sim Restio.*" "They shall be Buccdæ whether they will or no, before I be Restio." The Jews employed flagellation as a punishment, but never as a voluntary act of devotional exercise. This practice was unknown to the primitive Christians; neither does it appear that the first hermits of the Thebaid added self-flagellation to the different modes of penance with which they tortured their body. The rules of the first monasteries in the East, drawn up by St. Anthony, Paphnutius, Macarius, and others, contain no ordinance as to that kind of discipline, neither is it mentioned in the original regulations of the Benedictine order, the first that was established in the West. The legends which describe the lives of the saints who lived before the beginning of the 5th century never speak of self-flagellation amongst the various torments which the above-mentioned saints inflicted on themselves.

The first known instances of this kind of self-mortification occur about A.D. 400, and from that time they became continually more frequent till the year 1056, when Cardinal Peter Damian de Honestis promoted by all his influence the practice of self-flagellation, which the learned author of the 'Ecclesiastical Annals,' Cardinal Baronius, calls "a laudable usage of the faithful." Damian's efforts were attended with great success, and the chroniclers relate that persons of religious dispositions were seen everywhere armed with whips, thongs, and rods, lacerating their own skins in order to draw down on themselves the blessings of Heaven. This practice began to spread so widely that many of the less bigoted clergymen endeavoured to discountenance it, but unsuccessfully, and it became every day more prevalent among the besotted crowds of that dark age. About the year 1260 the intoxication was complete. People being no longer satisfied to practise similar mortifications in private, began to perform them in public on pretence of greater humiliation. Regular associations and fraternities were formed for that purpose; and the extravagancies which they committed were of such a nature that even the contemporary writers, although accustomed to such scenes, seem to have been struck with astonishment. The monk of St. Justina, the first author who gives a circumstantial account of these fanatics, says the practice was attended with good effects.

"Then," continues the same author, "those who were at enmity with one another became friends. Usurers and robbers hastened to restore their ill-gotten riches to their right owners. Others who were contaminated with different crimes confessed them with humility, and renounced their vanities. Jails were opened, prisoners were set free, and banished persons permitted to return to their native habitations."

This sudden repentance was the effect of the terror inspired by the general belief that the end of the world was at hand. Such mental fever could not last very long, and indeed it seems to have soon subsided. But in the 14th century, when the imaginations of the people were excited by the terrible pestilence known under the appellation of the black death, which desolated all Europe during that century, the flagellation mania broke out with new fury. The flagellants held that flagellation was of equal virtue with baptism, that the law of Christ was about to be abolished, and a new law, enjoining the baptism of blood, to be administered by whipping, was to be substituted in its place. Not only all the scenes of the 13th century were re-enacted, but the excesses of fanaticism became even worse than before. The flagellants spread over all Europe, and a band of them reached London in the reign of Edward III. Their number consisted of 120 men and women. Each day at an appointed hour they assembled, ranged themselves in two lines, and paraded the streets scourging their naked shoulders and chanting a hymn. At a given signal, all with the exception of the last, threw themselves flat on the ground; and he who was last, as he passed by his companions, gave each a lash, and then also lay down. The others followed in succession till every individual in his turn had received a stroke from the whole brotherhood. The citizens of London gazed and marvelled, pitied and commended; but they went no farther. Their faith was too weak, or their skins too delicate; and they allowed the strangers to monopolise all the merits of such a religious exercise. The missionaries did not make a single convert, and were obliged to return without any other success than the conviction of having done their duty to an unbelieving generation. (Stow's 'Annals.')

Early in the 15th century they re-appeared in Germany, and their leader, Conrad Schmidt, was burnt as a heretic in 1414; but the sect continued to exist nearly throughout the century. Their doctrines, however, were widely different from those of their predecessors. They taught that the Roman Catholic belief in the efficacy of the sacrament, purgatory, and prayers for the dead were false; and that faith and flagellation, with a belief in the apostle's creed, were alone necessary for salvation.

The purity of the first flagellants was not long preserved by their followers, and it was but natural that a fanatical rabble, who thought that self-torment was a sufficient atonement for all possible sins, should fall into great excesses. The flagellants were soon accused of many crimes; the celebrated Gerson attacked them in his writings, and Pope Clement VII. declared them heretics, and thundered out anathemas against them. The flagellants were persecuted everywhere, and many of them were burnt as heretics. It was, however, with great difficulty that this sect was completely extirpated. For further particulars about the flagellants see all the ecclesiastical histories; and also Jacques Boileau, 'Histoire des Flagellans;' an English paraphrase of the same work appeared under the title 'Memorials of Human Superstition by one who is not a Doctor of the Sorbonne;' see also Muratori's 'Antiquit. Ital. Medii Ævi,' and Mosheim's 'Ecclesiastical History.'

FLA'GEOLET, a small pipe, or musical instrument, of the flute kind, played on by means of a mouthpiece, in the manner of the old English flute and pitch-pipe. Its compass is two octaves, from F, the first space in the treble cleff, to F in altissimo. The scale of the *quadrille flageolet* is rather more limited; and that of the *patent octave flageolet* is an octave higher than the ordinary instruments.

The *double flageolet* consists of two instruments, united by one mouthpiece, producing, as its name indicates, double notes. The use of the flageolet is now almost entirely confined to the ball-room; it is superseded by the octave flute, or *flauto piccolo*. [Flute.]

FLAKE WHITE. [Colouring Matters.]

FLAMBOYANT, a term employed by many writers to designate that style of French Gothic architecture which corresponds in time to what is commonly called the Perpendicular style in England. The name was given to it from the waving or flame-like curves of the tracery of the windows, &c. [Gothic Architecture.]

FLAME is the combustion of gaseous or of volatilised fluid or solid matter. It is attended with great heat, and sometimes with the evolution of much light; but the temperature may be intense when the light is feeble: this is the case with the flame of hydrogen gas, it being scarcely visible by daylight, though its heat is intense; the combustion of hydrogen is then an example of flame resulting from the chemical action between it and the oxygen of the air. As there is no solid matter in the flame of this gas, the light which it yields is inconsiderable; but it is greatly increased by dusting finely divided charcoal into the flame.

In the burning of a candle, the wax or tallow being first rendered fluid by heat, rises in the wick, and although the wick supplies some hydrogen and carbon, by far the greater portion of these is yielded by the wax or tallow, which burn by the assistance of the oxygen of the air. The supply of hot vapour diminishes as it ascends, and eventually fails, and hence the flame of a candle gradually tapers to a point and then ceases.

Two opinions have been entertained as to the mode in which flame is produced and propagated. According to Sir H. Davy, the flame of combustible bodies "must be considered as the combustion of an explosive mixture of inflammable gas or vapour and air; for it cannot be regarded as a mere combustion at the surface of contact of the inflammable matter; and the fact is proved by holding a taper or a piece of burning phosphorus within a large flame made by the combustion of alcohol; the flame of the candle or of the phosphorus will appear in the centre of the other flame, proving that there is oxygen even in its interior part." ('On the Safety-Lamp,' p. 45.)

In the opinion of Mr. Sym ('Annals of Phil.,' vol. viii. p. 321), "the internal part of the flame is comparatively cool, the actual combustion being diffused over the surface, and concentrated at the apex." Mr. Sym adduces many curious and important experiments in proof of his opinion; but the most decisive facts in its favour are those related by Mr. Davies ('Ann. Phil.,' vol. x., p. 447), and they appear fully to warrant the inference he has deduced from them, that the interior of flame will not support combustion, and that on account of its containing little or no oxygen.

A piece of phosphorus was placed upon a small wooden stand in a Wedgwood dish; spirit of wine was then poured into the dish in such a manner that it did not reach the phosphorus. The spirit of wine was lighted, and its flame completely enveloped the combustible body. In the course of a few seconds the phosphorus became fluid, and remained in that state upon the stand, and never in a single instance inflamed, until the alcohol was consumed or its flame extinguished, though in several instances the spirit of wine continued to burn for three or four minutes. The phosphorus always burst into a vigorous flame when the spirit of wine was extinguished. When the flame of the spirit of wine was blown upon, so that the edge of it came in contact with the phosphorus, the phosphorus immediately burst into a flame; but the flame was instantly extinguished and the boiling resumed, as soon as the flame of the alcohol was restored to its natural position.

Mr. Davies states also that a lighted wax taper surrounded by alcohol was extinguished when the alcohol was inflamed.

That flame is merely a thin film of white hot vapour, and that its combustion is entirely superficial, while inflammable matter is contained within which cannot burn for want of oxygen, is proved by inserting one end of a small hollow glass tube into the dark central portion of the flame of a large candle or of a gas-light; the interior unburnt vapour or gas will escape through it, and may be lighted at the other end of the tube.

A most intense light, employed by Lieutenant Drummond in geodetical operations, is produced by passing a stream of oxygen gas directed through the flame of alcohol upon lime turned into the form of small balls. He found the light emitted by the lime when exposed to this intense heat to be 83 times the intensity of the brightest part of the flame of an argand burner of the best construction and supplied with the finest oil. Lime has since been used with the oxy-hydrogen blowpipe for the illumination of the solar microscope.

The brilliancy of flame is much diminished by various cooling processes: thus, when a piece of glass is put over or into the flame of a candle, it becomes covered with charcoal in the state of soot, which the diminished heat of the flame is incapable of burning. This takes place to a much greater extent with oil and tallow than with alcohol; the latter containing less carbon and more hydrogen than the former, its carbon is not so readily deposited by cooling.

It is on the cooling power of the metals with regard to flame, and especially of wire-gauze, that the construction of the safety-lamp depends. [Safety-Lamp.] The uses to which flame is applied are numerous and highly important; it is employed for the purpose of giving heat in reverberatory furnaces and in the blowpipe, and for that of yielding light in gas- and oil-lamps and candles. It is to be observed, that flame is produced by various other chemical processes, and by other means than the combustion of substances containing hydrogen and carbon, though the latter are the elements from which it is obtained for all the numerous purposes of common life and manufactures.

FLAMEN, FLAMINES, one of the orders of priesthood in ancient Rome, like the Salii, the Feciales, and others, instituted, according to tradition, by Numa Pompilius. The Flamines were each destined to the service of some particular deity; there was the Flamen Dialis who was consecrated to the worship of Jupiter, and was the first in rank, the Flamen Martialis, who attended to the worship of Mars, Flamen Quirinalis, &c. They enjoyed great consideration, and their wives, called Flaminicæ, attended the sacrifices and other sacred ceremonies. But with their privileges they were subjected to great restrictions; they could not be absent from the city more than a single night; nor from their own beds more than two nights consecutively; nor mount on horseback; nor touch a horse, a dog, or a corpse; nor swear an oath; nor wear a ring with stones, &c.; and if his wife died the Flamen was compelled to resign his office. The Flamines were distinguished by a peculiar pileus, or hat, of a conical shape, which was fastened under the chin. Their number, which was originally only three, was increased afterwards as new gods were introduced, and at last even the emperors, being deified after death, had a Flamen appointed for them. The Flamines were chosen, the three named above from among the patricians, the others from the plebeians.

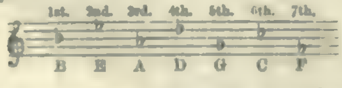
FLANK of a bastion, &c., is the term applied in fortification to that portion of a work, the fire from which being in the direction of, and in front of, any work, would take in flank the attacking party, thereby most materially aiding in the defence, for it is evident that without such works to sweep by their fire along the foot of a high revetment-wall, or parapet, the attacking party would, when they reached such a position, be safe from the besieged, except in so far as hand-grenades and shells rolled over the parapet could reach them and might place their scaling ladders, or carry on mining operations to break the ramparts, in perfect security. In fact, such has been done in Indian forts, where from the curvature or irregularity of the wall, the fire from the adjacent flanking towers was ineffective. The line of defence, or length of line flanked by a work, will depend on the range, &c., of the weapons used; with the old musket it was considered that 180 yards was the greatest length admissible. [BASTION.]

FLANNEL MANUFACTURE. Flannel is made of worsted yarn, spun much more loosely than that for most kinds of garment cloths, and finished with a less amount of dressing; but the manufacturing operations are nearly the same in principle: and therefore it will suffice to refer to WOOLLEN AND WORSTED MANUFACTURE for an account of the machinery and processes employed. It may be well, however, in this place, to mention a few specialities in relation to this branch of industry. Wales is the country in which flannel was originally made; and the flannel produced there is still held in high repute for inner vests and other purposes. This superior flannel is made chiefly about the neighbourhood of Welchpool and Newtown; it is better than most of the English, but not so cheap. The finest is made from the fleece of the Welch mountain sheep. Lancashire, and especially Rochdale and its neighbourhood, is the district where flannels are made more extensively than in any other part of the British dominions, perhaps than in any in the world. They are woven in that county in a great variety of width and substance; such as the thin gauze, the medium, the thick, the double-raised, and the swanskin flannels; some for home consumption, some chiefly for foreign. Machinery is more generally used here than elsewhere in the manufacture; that is, the mule for spinning, and the power-loom for weaving. Saddleworth, and the adjacent district of West Yorkshire, are remarkable for the manufacture of very fine flannels, which find a ready sale at good prices in London. A few cheap and common flannels are made in the Leeds district, retaining the natural colour of the wool. In the West of England, white and dyed flannels are made in small quantity, partaking somewhat of the quality of light cloth. Ireland produces coarse flannels, called *Galways*, made of Irish-grown wool, and adapted for the native population. Of continental nations, France and Belgium produce the best flannels; the fine light flannels of the first-named country are well adapted for dyeing or printing.

The extent of the exportation of flannels cannot be ascertained from the Board of Trade returns, seeing that they are combined as one among several items belonging to the class of Worsted Goods.

FLASK. In chemistry, a glass vessel of a more or less globular form, with a neck, used for heating liquids.

FLAT, in music, a character originally represented by a small *b*, though time has somewhat altered its outline, and the following is now its form—♭. The Flat is used to lower, or depress, by the degree of a semitone, any note in the natural scale. In ancient music, before the character of the Natural was introduced, the Flat was employed to reduce any note which had been made sharp, to its natural state. Where Flats are placed at the clef, they are always taken in the following order:—



When a Flat, not appearing at the clef, occurs in any other part of the composition, it only affects the bar in which it is placed, and is called an *Accidental Flat.*

The DOUBLE FLAT ( ) is frequently employed in very chromatic music. It lowers a note two semitones below its natural state. Thus, B *double-flat* ( ) is, in fact, A *natural*, &c. This character is used chiefly in Enharmonic modulation [ENHARMONIC], in which it is practically convenient, if not absolutely necessary, occasionally to have an additional name for each note in the diatonic and chromatic scales.

FLAVIN. [UREA, *Diphenyl-urea.*]

FLAVINDIN. [INDIGO.]

FLAX (*Linum usitatissimum*) is an annual plant, cultivated from time immemorial for its textile fibres, which are spun into thread and woven into linen cloth. It has a green stem from a foot and a half to two feet high, and a blue flower, which is succeeded by a capsule containing ten flat oblong seeds of a brown colour, from which an oil is expressed, which is extensively used in manufactures and in painting. There are several varieties of flax cultivated; the best seed comes from Riga and from Holland. As the different varieties arrive at maturity at different times, and the stem rises to different heights, it is very essential that the seed be not mixed, as this would occasion great inconvenience and loss in the pulling of the flax. There is a very fine long variety which is cultivated in the neighbourhood of Courtray, in Flanders; it requires a very good soil to grow in, and the stem is so long and slender that if it were not supported the least wind would break it and lay it flat, in which case the quality of the flax would be much impaired and the quantity reduced. To prevent this, short stakes are driven into the ground in a line at eight or ten feet from each other, and long slender rods are tied to them with oziers about a foot or eighteen inches from the ground, forming a slight railing to support the flax: a number of these are placed in the same manner at a short distance from each other in parallel lines all over the field, and the flax is thus prevented from being beat down. A better method, which is not commonly adopted, is to have stakes in regular rows, and thin ropes tied to them instead of rods: by having these lengthways and others across them at right angles, a kind of large net is spread over the whole field, and none of the flax can possibly be laid flat. By using cheap rope or strong tar twine from old cables, the expense is not very great, and much less room is taken up than by the rods. When the flax is pulled, the stakes are taken up, and removed to a dry place till they are wanted again.

The most common variety of flax is of a moderate length with a stronger stem: if it is not sown very thick it will throw out branches at top and produce much seed: it is therefore a matter of calculation whether it will be most profitable to have finer flax with less seed, or an inferior quality with an abundance of seed.

There is a small variety which does not rise above a foot, grows fast, and ripens its seed sooner. When linseed is the principal object, this variety is preferred; but the flax is shorter and also coarser.

Another variety of flax has a perennial root, and shoots out stems to a considerable height. It came originally from Siberia, and was much recommended at one time, but its cultivation did not spread. If it were sown in wide rows and kept free from weeds by hoeing, it might perhaps be profitably cultivated for the seed; and if the flax is inferior in quality, it might still be of some value for coarse manufactures; it requires however to be renewed every three or four years and sown in fresh ground.

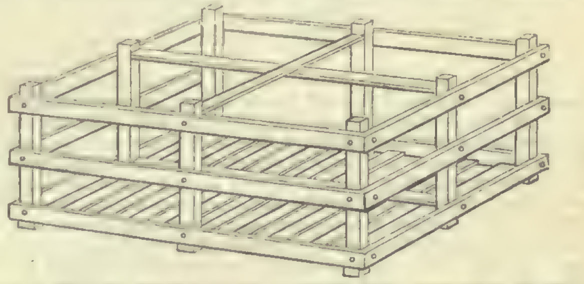
The soil best adapted to the growth of flax is a deep rich loam in which there is much vegetable mould. It should be mellow and loose to a considerable depth, with a sound bottom, neither too dry nor too moist; either extreme infallibly destroys the flax; it is therefore not suited either to hot gravelly soils or cold wet clays, but any other soil may be so tilled and prepared as to produce good flax. It thrives well in the rich alluvial land of Zealand and the polders, but it is also raised with great success in the light sands of Flanders, but much more careful tillage and manuring are required. The land on which flax is sown must be very free from weeds, the weeding of this crop being a very important part of the expense of cultivation. These circumstances suggest the best mode of preparing the land. A long fallow, such as is sometimes given to the land in Essex, including two winters and a summer, may be a good preparation on the heavier loams, which should be trench ploughed and worked deep; the manure should be dung fully rotten, or a compost of earth and dung; it should be put on the land in autumn, and well incorporated before the seed is sown. If the land is sufficiently clean, a crop of potatoes well manured may be substituted with advantage for the fallow; but at least double the usual quantity of dung should be given to this crop that enough may remain in the ground for the flax. Lime may be used if the soil contains a great portion of clay; but in the lighter loams there is some doubt of its advantage for flax. At all events it should not be used immediately before the flax is sown, but for some previous crop. Peat-ashes are excellent; they improve the soil and keep off insects, which are apt to injure the roots of the flax. For want of peat-ashes, those made by the burning of weeds and earth in a smothered fire are a good substitute. But the most effective manure is the sweepings of the streets in towns mixed with the emptying of privies and the cleaning out of the butchers' stalls and shambles. On light soils much manure is required; and where night soil cannot be obtained in sufficient quantities, rape cakes, from which the oil has been expressed, dissolved in cows' urine, form the best manure. In many parts of Flanders 500 rape cakes are used for every acre of flax, besides the usual quantity of Dutch ashes and of liquid manure, which is the drainings of dunghills and the urine of cattle collected in a cistern and allowed to become putrid.

In southern climates flax is sown before winter, because too great heat would destroy it. It is then pulled before the heat of summer. In northern climates the frost, and especially the alternations of frost and thaw in the early part of spring, would cause the flax to perish; it is consequently sown as early in spring as may be, so as to avoid the effect of hard frost. This is in April in Great Britain and Ireland, and in Holland and Flanders. In no country is the ground better prepared for the growth of flax than in Flanders; and it may therefore be interesting to follow the whole process of Flemish cultivation for several crops preparatory to that of flax, which is the most important produce in that country, and that which, when well managed, gives the greatest profit to the farmer. The best flax grows near Courtray. The soil is a good deep loam, rather light than heavy. It is not naturally so rich as the soil of the polders in Flanders and in Zealand, but the tillage and cultivation are far more perfect, and the produce, if not more abundant, is of a finer quality. Every preceding crop has a reference to the flax, and is so cultivated as to improve the texture of the soil, which is abundantly manured in order to leave a considerable surplus in the ground. If the land has not been trenched all over with the spade to the depth of eighteen or twenty inches, it has been equally well stirred by the narrow open drains which are dug out twelve or fifteen inches deep every year between the stitches in which it is laid by the plough. These drains, or water furrows, are a foot wide, and from a foot to eighteen inches deep. The earth taken out of them is spread evenly over the land after the corn is sown. When the ground is ploughed again, care is taken that the place of these water-furrows shall be shifted a foot on each side. Thus in six years the whole soil is deepened and thoroughly mixed with whatever manure has been put on. This produces the same effect as trenching, and even more perfectly. The whole of the land in which the best flax grows has been so treated for several generations, and may be looked upon as a species of compost eighteen inches deep. Potatoes or colza are usually planted with a double portion of manure, after which wheat is sown, slightly manured; then rye with turnips sown the same year after the rye. These are taken up in September or October, and stored for winter use. The land has been well weeded while the turnips were growing, and all the manure is decomposed and mixed with the soil. It is ploughed in stitches before winter, some manure having been previously spread over it if necessary; and it is left exposed to the mellowing effects of frost and snow. As soon as the winter is over, and the snow is melted, the final preparation goes on. Deep ploughing and harrowing further divide and pulverise it: the surface is laid as level and smooth as possible; and if there is no fear of too much wet, which in this light loam soon disappears, the whole is laid flat and level as a bowling-green, or else divided into beds with water-furrows between them. On this the liquid manure is poured out, and the Dutch ashes spread if any are used, or the rape-cakes, as mentioned before. The harrows are drawn over the land, and it is left so a few days that the manure may sink in. It is then again harrowed and the linseed is sown broadcast by hand, very thick and even, about one hundredweight and a half to the acre. A bush-harrow or a hurdle is drawn over, merely to cover the seed, which would not vegetate if it were buried half an inch deep. According to the state of the land it is rolled or not, or the seed is trodden in by men, as is done with fine seeds in gardens. This is only in the lightest soils. Most commonly the traineau is drawn over the land. This is a wooden frame with boards nailed closely over it, which is drawn flat over the ground to level and gently press it. In a short time the plants of flax come up thick and evenly, and with them also some weeds. As soon as the flax is a few inches high the weeds are carefully taken out by women and children, who do this work on their hands and knees, both to see the weeds better and not to hurt the flax with their feet. They tie coarse pieces of cloth round their knees, and creep on with their face to the wind, if possible. This is done that the tender flax, which has been bent down by creeping over it, may be assisted by the wind in rising. This shows what minute circumstances are attended to by this industrious people. The weeding is repeated till the flax is too high to allow of it.

The seed which is used is generally obtained from Riga, it being found that the flax raised from home-grown seed is inferior after the first year. But many intelligent men maintain that if a piece of ground were sown thin with linseed, so that the flax could rise with a strong stem, and branch out, and if the seed were allowed to ripen, the Flemish seed would be as good as that from Riga; but it still remains to be proved whether it would be cheaper to raise it or to import it.

When the flax begins to get yellow at the bottom of the stem it is time to pull it, if very fine flax is desired, such as is made into thread for lace or fine cambric; but then the seed will be of little or no value. It is therefore generally left standing until the capsules which contain the seed are fully grown and the seed formed. Every flax-grower judges for himself what is most profitable on the whole. The pulling then begins, which is done carefully by small handsful at a time. These are laid upon the ground to dry, two and two obliquely across each other. Fine weather is essential to this part of the operation. Soon after this they are collected in larger bundles and placed with the root end on the ground, the bundles being slightly tied near the seed end; the other end is spread out that the air may have access, and the rain may not damage the flax. When sufficiently dry they are tied more firmly in the middle, and stacked in long narrow stacks on the ground. These stacks are built as wide as the bundles are long, and about eight or nine feet high. The length depends on the crop; they are seldom made above twenty or thirty feet long. If the field is extensive, several of these stacks are formed at regular distances; they are carefully thatched at top, and the ends, which are quite perpendicular, are kept up by means of two strong poles driven perpendicularly into the ground. These stacks look from a distance like short mud walls, such as are seen in Devonshire. This is the method adopted by those who defer the steeping till another season. Some carry the flax as soon as it is dry under a shed, and take off the capsules with the seed by *rippling*, which is drawing the flax through an iron comb fixed in a block of wood; the capsules which are too large to pass between the teeth of the comb are thus broken off and fall into a basket or on a cloth below. Sometimes, if the capsules are brittle, the seed is beaten out by means of a flat wooden bat like a small cricket-bat. The bundles are held by the root end, and the other end is laid on a board and turned round with the left hand, while the right hand with the bat breaks the capsules, and the linseed falls on a cloth below. The flax is then immediately steeped; but the most experienced flax-steepers defer this operation till the next season. In this case it is put in barns, and the seed is beat out at leisure in winter. When flax is housed, care must be taken that it be thoroughly dry; and if the seed is left on, which is an advantage to it, mice must be guarded against, for they are very fond of linseed, and would soon take away a good share of the profits by their depredations.

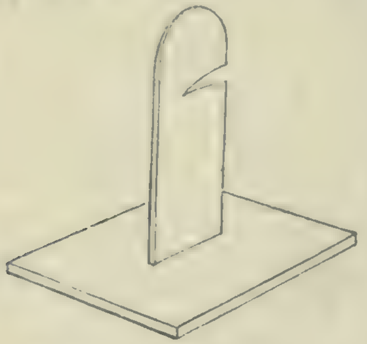
Steeping the flax is a very important process, which requires experience and skill to do it properly. The quality and colour of the flax depend much on the mode of steeping; and the strength of the fibre may be injured by an injudicious mode of performing this operation. The object of steeping is to separate the bark from the woody part of the stem, by dissolving a glutinous matter which causes it to adhere, and also destroying some minute vessels which are interwoven with the longitudinal fibres, and keep them together in a kind of web. A certain fermentation or incipient putrefaction is excited by the steeping, which must be carefully watched, and stopped at the right time. The usual mode of steeping is to place the bundles of flax horizontally in shallow pools or ditches of stagnant water, keeping them under water by means of poles or boards with stones or weights laid upon them. Water nearly putrid was supposed the most efficacious, and the mud was often laid over the flax to accelerate the decomposition: but this has been found to stain the flax, so that it was very difficult to bleach it or the linen made from it afterwards. The method adopted by the steepers of Courtray, where steeping flax is a distinct trade, is different. The bundles of flax are placed alternately with the seed end of the one to the root end of the other, the latter projecting a few inches: as many of these are tied together near both ends as form a thick bundle about a foot in diameter. A frame made of oak-rails nailed to strong upright pieces in the form of a box 10 feet square and 4 deep, is filled with these bundles set upright and closely packed. The whole is then immersed in the river, boards loaded with stones being placed upon the flax till the whole is sunk a little under the surface of the water. The bottom does not reach the ground, so that the water flows over and under it. There are posts driven in the river to keep the box in its place, and each steeper has a certain portion of the bank which is a valuable property. The flax takes somewhat longer time in steeping in this manner than it does in stagnant and putrid water, and it is asserted by those who adhere to the old method that the flax loses more weight; but the colour is so much finer that flax is sent to be steeped in the Lys from every part of Flanders. When it is supposed that the flax is nearly steeped sufficiently, which depends on the temperature of the air, the flax being sooner steeped in warm weather than in cold, it is examined carefully every day, and towards the latter part of the time several times in the day, in order to ascertain whether the fibres readily separate from the wood the whole length of the stem. As soon as this is the case the flax is taken out of the water: even a few hours more or less steeping than is necessary will make a difference in the value of the flax. If it is not steeped enough, it will not be easily scutched, and the wood will adhere to it. If it has been too long in the water, its strength is diminished, and more of it breaks into tow. The bundles are now untied, and the flax is spread evenly in rows



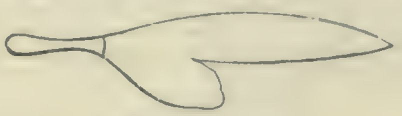
Frame in which the flax is packed to be steeped in the river Lys in Flanders.

slightly overlapping each other on a piece of clean smooth grass which has been mown or fed off close. Fine weather is essential to this part of the process, as rain would now much injure the flax. It is occasionally turned over, which is done dexterously by pushing a long slender rod under the rows and taking up the flax near the end which overlaps the next row and turning it quite over. Thus, when it is all turned, it overlaps as before, but in the contrary direction. It remains spread out upon the grass for a fortnight, more or less according to the season, till the woody part becomes brittle and some of the finest fibres separate from it of their own accord. It is then taken up, and as soon as it is quite dry it is tied up again in bundles, and carried into the barn to be broken and heckled at leisure during the winter.

In the domestic manufacture the flax is broken or scutched at home, when the weather prevents out-door work. The common break consists of four wooden swords fixed in a frame, and another frame with three swords which fit in the interstices of the first by means of a joint at one end. The flax is taken in the left hand and placed between the two frames, and the upper frame is pushed down briskly upon it. It breaks the flax in four places, and by moving the left hand and rapidly repeating the strokes with the right the whole handful is soon broken. It is then scutched by means of a board set upright in a block of wood so as to stand steady, in which is a horizontal slit about three feet from the ground, the edge of which is thin. The broken flax held in handsful in the left hand is inserted in this slit, so as to project to the right, and a flat wooden sword of a peculiar shape is held in the right hand; with this the flax is repeatedly struck close to the upright board, while the part which lies in the slit is continually changed by a motion of the left hand. This operation beats off all the pieces of the wood which still adhere to the fibre, without breaking it, and after a short time the flax is cleared of it and fit to be heckled. But the operations of breaking and scutching are tedious and laborious when thus executed by hand. A mill is now used (where large quantities of flax are required for manufactures), having three fluted cylinders, one of which is made to revolve by horse or water power and carries the other two round. The flax plants are passed between these cylinders while thus revolving, and the stalk, or *boon*, as it is technically called, is by this means completely broken without injuring the fibres. The scutching is accomplished in the same mill by means of four arms projecting from a horizontal axle, arranged so as to strike the boon in a slanting direction until the bark and other useless parts of the plant are beaten away. In the last process by which flax is prepared for the spinner, the *heckling*, the instrument employed, called the heckle, is a square piece of wood studded with rows of iron teeth about four inches long, and disposed in a quincunx order. The fineness of the heckle is chosen with reference to the quality of the flax, and heckles differing in this respect from each other are used at different stages of the dressing, the coarsest first, and the finest to give the last degree of smoothness and finish to the flax. The operation of heckling is performed by the workman grasping a handful of flax by the middle and drawing first one side or end and then the other through the teeth of the heckle until every particle of extraneous matter is removed, and the whole of the filaments are arranged in distinct, even, and parallel fibres.



Upright board to clear the flax of the wood.



Flat sword or scutcher.

The cultivation of flax in this country, notwithstanding the energetic advocacy of enthusiastic men, and even of societies established for the purpose, has been if anything declining. Mr. Warner, of Trimmingham, near North Walsham, in Norfolk, advocated the cultivation of the crop with great energy for several years, and induced many to attempt it: and in Ireland a society for the encouragement of its cultivation was supported by a government donation, and employed Belgian and other teachers to explain in the different localities the best method of cultivation. The system of steeping for weeks in order to effect the separation of the fibre, is now very generally displaced in this country by Schenk's method of soaking for a day or two in vats of warm water; and wherever manufactories on that plan have been established, and a market thus provided for the straw, the crop retains its place in our rotations. Grown after clover or almost any green crop, with diligent and cleanly tillage and liberal manuring, a crop of sufficient bulk is obtained to repay cultivation, but the peculiar and laborious character of its cultivation generally so far interferes with the ordinary economy of labour on our small farms, that it is not a general or increasing favourite with the British farmer.

FLÈCHE, a small work consisting of two faces, which form a salient angle. It is constructed at the foot or beyond the glacis of a place in order to give an advanced musquetry fire, when such is desirable from the conformation of the ground, to see down a small ravine or hollow for instance, or to enfilade a besieger's trenches.

FLETA is a commentary in Latin on the entire body of the English law, as it stood at the time when the author wrote. It is supposed to have been written about the thirteenth year of the reign of Edward I., as the statutes passed towards the end of his reign are not noticed, while that of Westminster II. is often quoted. The author gives as the reason for the title of his book, that it was written during his confinement in the Fleet Prison: who he was is not known. The author has followed Bracton in the matter and manner of his work, having adopted his plan, and in many instances transcribed whole pages from him. He also followed Glanville in many instances. Various obscure passages of both those writers are illustrated by Fleta. (Reeve's 'Eng. Law.')

The work was originally published by Selden from an ancient manuscript in the Cottonian Library, together with a small treatise in law French, entitled 'Fet Assavoir,' which is a collection of notes concerning proceedings in actions, and a learned dissertation by Selden himself. Two editions only have been published in England, one in 1647, the other in 1685, which last corrects many hundred errors which had been caused in the first edition by an unskilful copyist (Bridgman). It is also printed in Houard's collection. [BRITTON, in BIOG. DIV.] President Henault, in his 'Chronological Abridgment of the History of France,' tome i. p. 258, refers to Fleta as an historical authority.

FLEET PRISON, a metropolitan prison, pulled down in 1845, and so called from its being situated by the side of the river Fleet, now covered over. It was the prison to which persons were committed by the ecclesiastical courts, the courts of equity, and the Exchequer and Common Pleas; but was abolished by the 5 & 6 Vict. c. 22, which established the Queen's Prison (formerly the Queen's Bench Prison) as the only prison for debtors, bankrupts, and other persons who might formerly have been imprisoned in the Queen's Bench, the Fleet, or the Marshalsea prison.

FLEUR-DE-LIS, a term of blazonry for the flower which resembles an iris, and which, previously to the French Revolution, was borne first semée, and then three, as representing semée, in the arms of France. In old English it was called the *flower-de-luce*. Its origin and history have been variously stated by the French antiquaries. Some have considered it as the flower which grew on the banks of the river Lys, which separated Artois and France from Flanders; others state that Louis VII., who began his reign in 1137, first adopted it in allusion to his name of *Loys*, and because he was called *Ludovicus Florus*, or the Young. The coins of Louis VII. are allowed to be the first on which the *fleur-de-lis* appears, as well as upon his smaller or counter seal. The *fleur-de-lis* were originally borne semée, without regard to number: according to common belief Charles VI. was the first of the French monarchs who reduced them upon his shield to three. Le Blanc, however, remarks that three fleur-de-lis only occur upon the seal of Philip de Valois, as well as upon an impression of a seal of John, King of France, appended to a charter of 1355. Much upon the history of the fleur-de-lis may be seen in Furetière's 'Dictionnaire Universel,' v. 'Lis;' and more especially in Rey's 'Histoire du Drapeau, des Couleurs, et des Insignes de la Monarchie Française,' 8vo, Par. 1837, tom. ii. Upon crowns and the tops of sceptres the *fleur-de-lis* was used by other nations as well as France from a very early period.

FLEXIBILITY is a property of bodies by which they yield transversely, on the application of some power. There is no substance that is not more or less flexible, because there is no substance that is perfectly rigid, and if the rigidity of a body be imperfect it must be to some extent flexible. This property is distinct from ELASTICITY, as it does not necessarily follow that the bodies acted on recover their original figures when the power is removed.

Fibres of wool, silk, hair, and the like, possess this property in a high degree; rods of wood, metal, and stone are flexible, and those of the two last materials are more particularly so when heated. The property is so much the more sensible as the fibres or rods are longer.

When a body instead of yielding and changing its form under the action of a force, breaks, it is said to be *brittle*. These qualities of flexibility and brittleness are present in various degree in different bodies, and under certain conditions either property may be imparted to the same body; brittleness, however, being rather a consequence of hardness than an independent property of matter. If iron, steel, brass, and copper, be heated and suddenly cooled in cold water, they become brittle, but if after being heated they are buried in hot sand, and allowed to cool slowly, they lose their brittleness and become flexible.

The deflexions of beams or bars in vertical and in horizontal positions, when strained by weights, will be noticed under MATERIALS, STRENGTH OF; and the employment of the fibres of hemp and of iron or copper wire in the formation of ropes will be explained under ROPES. Ropes made of metal are said to be even more flexible than those made of hemp, the capabilities of suspending weights being equal, and the former being, of course, less in circumference than the latter.

The mathematical theory for the vibrations which may take place in a thread which is perfectly flexible, when small forces are applied to all its points; and the investigation of formulæ for determining the position and velocities of the points at the end of a given time, may be seen in Poisson's 'Traité de Mécanique,' No. 482, &c., edit. 1833.

FLEXURE, CONTRARY. A point of contrary flexure in a curve is that at which the branch of the curve ceases to present convexity to a straight line without it, and begins to present concavity, or vice versâ. [CURVE.] But when a straight line passes *through* a point of contrary flexure, the curve presents either convexity on both sides or concavity on both sides.

The algebraical test of a point of contrary flexure is a change of sign in the second differential coefficient of either of the two, abscissa or ordinate, with respect to the other. It is frequently stated, in works on the differential calculus, that the sole test of such a point is $\frac{d^2y}{dx^2}=0$, where x and y are the abscissa and ordinate. This is not correct; the above equation may be true when there is no contrary flexure, and there may be contrary flexures when the above is not true. It is necessary and sufficient for a point of contrary flexure that $\frac{d^2y}{dx^2}$ should change its sign, which cannot be except when it is nothing or infinite. Examine therefore all the roots of the two equations,

$$\frac{d^2y}{dx^2}=0 \qquad \text{and} \qquad \frac{1}{\frac{d^2y}{dx^2}}=0$$

and such of them as are accompanied by change of sign give points of contrary flexure.

For instance, let the equation of the curve be

$$y=3x^5-20x^4+50x^3-60x^2$$

$$\frac{d^2y}{dx^2}=60\,(x^3-4x^2+5x-2)=60\,(x-1)^2\,(x-2)$$

then $\frac{d^2y}{dx^2}=0$ when $x=1$ and when $x=2$: but there is only a point of contrary flexure when $x=2$, for when $x=1$ there is no change of sign.

FLEXURE OF COLUMNS. [MATERIALS, STRENGTH OF.]

FLIBUSTIER. [BUCCANEERS.]

FLINT-GLASS. [GLASS.]

FLINTS, LIQUOR OF, is a solution of flint or silica in the alkali potash; it is prepared by fusing together a mixture of four parts of hydrate of potash and one part of powdered flint or fine sand. When a part of the fluid compound is poured out of the crucible, crystals are formed in the residual portion, which, according to Berzelius, are composed of one equivalent of each of its constituents. This compound, sometimes called silicate of potash, silica being regarded as an acid, is soluble in water, and when sulphuric, nitric, or other powerful acids are added to it, hydrate of silica is precipitated.

FLOOK. [ANCHOR.]

FLOOR-CLOTH is made partly of hemp and partly of flax, the former being the cheaper of the two, but the latter better fitted to retain the oil and paint on the surface. As a means of avoiding the necessity for seams of joinings in the cloth, looms are constructed expressly for the weaving of the canvas, of the greatest width likely to be required. As brought to the floor-cloth factories, the pieces of canvas have generally one of three scales of dimensions: 100 yards long by 6 wide, 108 yards by 7, 113 yards by 8. The flax and hemp are spun, and the canvas woven, almost entirely in Scotland, chiefly at Dundee; and the degree of fineness is generally such as to present about 16 or 18 threads to the linear inch.

The canvas, throughout the subsequent operations, retains the same width as was given to it in the loom; but it is cut into pieces varying from 60 to 100 feet long: each of these pieces has to be stretched over a frame in a vertical position; and in most of the factories there is a large number of such frames, some 100 feet long by 18 or 20 high, others 60 feet long by 24 high. As a means of transferring the canvas to these frames, it is, when the bales are opened, cut to the proper length, laid down on the floor of a large room, and coiled round a long wooden roller about 5 inches in diameter; this roller is then lifted up vertically and removed close to the frame; one edge of the canvas is nailed or hooked to one edge of the frame, and the roller is made to travel onwards and to revolve in such a manner as to give off the canvas as fast as the latter can be hooked to the upper horizontal bar of the frame; when all is uncoiled and the canvas hooked on all four of its edges, the sides of the frame are so drawn by winches and levers as to stretch the canvas to a degree of tightness nearly equal to that of a drum, notwithstanding the extent of the surface (from 1500 to 1800 square feet). Here the canvas remains many weeks, during most of the processes.

Before the imprinting of the pattern which forms the most conspicuous feature in floor-cloth, the surface of the canvas requires a great deal of preparation, to render it smooth and durable. The pattern is applied on one surface only; but both surfaces are painted and prepared, the back before the front. A wash of melted size is applied by means of a brush to each surface; and, while this is yet wet, the surface is well rubbed with a flat piece of pumice-stone, whereby the little irregularities of the canvas are worn down, and a foundation is laid for the oil and colour afterwards to be applied. To work over so large an extent of surface, the workmen are provided with narrow scaffoldings, built up in front of, but not in contact with, the surface of the canvas: one scaffold being in front and another behind the canvas.

When the size-preparation is dried, the painting begins. The paint employed consists of the same mineral colours as those used in house-painting, and, like them, mixed with linseed oil; but it is much thicker or stiffer in consistence, and has very little turpentine added to it. The first layer of paint is applied with a trowel; or rather, the paint is dabbed on in large masses here and there, by means of a brush, and then levelled and spread by means of a kind of trowel 12 or 14 inches in length. Ten or twelve days are required for this thick coating to dry; and at the expiration of this time a second coating is laid on, thinner than the former, and applied with a brush instead of a trowel. These two layers of paint are all which the back or hinder surface of the canvas receives; but the front or face receives a greater thickness, and undergoes a greater number of processes. For instance, after the sizing, the surface is rubbed down with pumice-stone; then comes the trowel-colour, followed by a second rubbing with pumice; and then two, three, or more layers of colour, applied with a brush, each coating being followed by a rubbing with pumice before the next one is applied. The surface has by this time acquired a great degree of smoothness, and the general substance suppleness and pliability.

The prepared canvas is next removed from its vertical position in the frame, and wrapped round a roller, which is so placed as to allow the canvas to be uncoiled and spread out on a table to be printed. The printing of floor-cloth is conducted much on the same principle as that of paper-hangings for rooms. [PAPER-HANGINGS.] Both are examples of colour-printing; that is, the successive application of two or more blocks or engraved surfaces, each one giving a different part of the device from the others, and being supplied with paint of a different colour. In the infancy of this art the pattern was given by means of stencil-plates; thin plates of metal or of pasteboard were pierced with holes at the parts intended to form the pattern, and the paint was so applied as to fall through these holes upon the surface of the canvas spread out beneath. It was about a century ago that the use of wood blocks superseded that of stencil-plates for this purpose. The first block so employed was about 15 inches square, and had a simple device of zigzag lines cut upon its surface; when this was pressed face downwards on a cushion coated with wet paint, it took up a layer on all the raised parts of the device, and was then in a fit state to impart its impress to the canvas. The increased complexity arising from the employment of several colours was a feature of later introduction.

As at present conducted, the printing of floor-cloth with several colours requires much care on the part of the designer before the painter enters on his department. In the first place, the device is carefully drawn on the full scale on a stiff sheet of paper, and is coloured fully in every part according to the exact appearance which it is intended to present on the canvas. A second piece of paper is placed under this, and with a pin or pricker a series of holes is made through both papers, following the outlines of the pattern so far as regards one colour, which we may suppose to be green; another blank paper is placed under the pattern in lieu of the former, and the outlines of another coloured portion of the device are marked through both papers with the pricker; and so on as many times as there are colours, the outline of each colour being transferred to a paper distinct from the others. An equal number of blocks of wood are then prepared; these consist of two thicknesses of white deal and one of pear-tree wood, ranged at right angles with respect to the grain, to prevent warping; they are about fifteen inches square, by two and a half in thickness, and the pear-tree surface is the one on which the engraving is to be executed. One of the pricked papers is laid down on a prepared block, and a little bag containing pounce or pounded charcoal is daubed all over it; the powder enters the pin-holes, and leaves upon the surface of the wood a series of dots sufficient to guide the carver in working out the design, which he does by cutting away all the surface except where the lines of device are marked. All the other blocks are treated in the same way; and it is easy to see that each one is left uncut at those parts which are cut away in all the others, so as to avoid confusion of colours.

The blocks (which we will suppose to be four for one pattern, red, yellow, blue, and green) being ready, and the prepared canvas spread out on a flat table, the printing commences. The paint (say red) is applied with a brush to the surface of a pad or cushion formed of flannel covered with floor-cloth; the block, held by a handle at the back, is placed face downwards on this cushion, and the layer of paint thus obtained is transferred to the surface of the canvas by pressing the block smartly down on the latter. A second impression is made in a similar way by the side of, and close to, the first; and so on throughout the length and breadth of the canvas; each impression being about 15 inches square. The proper junction, or register, of the successive impressions is aided by pins at the corners of the blocks. When the whole surface is thus printed with one colour, all the other three are similarly applied in succession. Such would likewise be the case if the number of colours was more than four; but the greater the number the greater would be the care necessary in adjusting the numerous partial impressions so as to ensure a proper arrangement of the whole.

In printing floor-cloth for passages and stairs, where the width seldom exceeds a yard, the canvas is prepared in the frames as in other cases; but it is cut up into strips before being printed, and has usually a border given to its pattern by means of blocks much narrower than those employed in other cases. Where there are large patches of one colour in the pattern of floor-cloth, they are not given by smooth surfaces on the block, but by means of little projecting squares technically called teeth; the reason for this is, that if a surface two or more inches square were laid on wet paint, it would not take up the paint equally, but would exhibit it in an unequal splat; whereas, if the surface were broken up into a number of smaller surfaces by means of lines cut in various directions, these lines would act as air-vents, and the paint would be taken up pretty equally by the little squares or teeth.

One among the features which distinguish cheap oil-cloth (so-called) from good, is the hastiness with which the processes are conducted; the paint has often insufficient time for drying, and is sold for use before it is fitted to bear the friction of the feet. It has been suggested, with some probability, that floor-cloth, especially when thus insufficiently dried, may tend to rot the boards of a flooring in a damp room, by preventing the free escape of vapour.

Mr. Loudon ('Encyclop. of Cottage and Villa Architecture,' p. 345) notices a suggestion for the use of paper instead of floor-cloth or carpet. The carpet, according to this suggestion, is formed in the first instance of any fragmentary pieces of linen, cotton, canvas, or other material, sewn up to the required size. This cloth is stretched on the floor of a large room, and kept down in its place by being pasted round the edges. On this foundation stout paper is pasted; two thicknesses being applied in every part, with the joints so arranged as to be but little perceptible. On this a surface of wall paper is pasted; and here an opportunity for the exercise of taste is afforded, since a variety of pleasing patterns may be obtained by the judicious combination of fragments which are in themselves of very little account. When the pattern is thus far produced, it is coated twice with warm melted size, applied so as to soak into every part of the paper, and to prepare it for the reception of the varnish. One or more coatings of boiled linseed oil are applied after the size, and to the oil succeeds copal varnish. Of the floor-covering so produced it is said, "these carpets are portable, and will roll up with about the same ease as oil-cloth; they are very durable, are easily cleaned, and if made of well-chosen patterns have a very handsome appearance. Where labour is cheap the cost will be very trifling; the materials being of little value, and the expense consisting chiefly in the time requisite to put them together. Where cloth cannot be easily procured, the carpet may be made by pasting paper to painted boards; when by repeated coats of paper it has become strong and firm, it will separate from the paint and will be as durable as if mounted on any kind of cloth. For earth, brick, or stone floors, in order to render them impervious to damp, these carpets may be made with two faces, by pasting paper on both sides of the cloth which forms their basis, and well oiling or varnishing them on the under as well as the upper surface; they may also be bound with leather or any strong substance, to prevent moisture from penetrating to the paste."

It has also been more than once suggested, that 'Geographical carpets' might advantageously be constructed for school-rooms and similar apartments. By this term is meant the employment of a carpet or covering in which the lines of a map are substituted for a regular pattern. There would, as Mr. Loudon has stated, be a good deal of difficulty in working out the idea, since it would have to be decided whether the map should be *printed* before being laid down as a carpet, or filled in by hand afterwards. The choice of material too, whether linen, holland, or paper, would be attended with some difficulty; but such a map, especially if the northern portion of it were directed to the northern side of the room, would not be without its value in rendering the position of a country or district familiar to the inmates of the room.

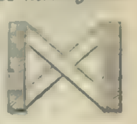
Messrs. Goodyear have recently patented a new kind of floor-covering, intended to combine at once the qualities of durability, softness, elasticity, and cheapness. Carpets are expensive, and not adapted for halls or public rooms; floor-cloth is wanting in softness and elasticity. It was to meet this want that the substance called *Kamptulicon* was invented some years ago. Many persons consider, however, that the kamptulicon, often used the floors of churches and other large buildings, has a tendency to become brittle after some time of usage. Be this as it may, Messrs. Goodyear have devised a mode of combining cork, cotton, wool, and other fibrous materials, with india-rubber, and spreading the mixture upon a back or ground of canvas or woollen. In this state, the carpet or floor-covering undergoes a kind of embossing process, plain or in colours. When thoroughly dried, it is said to have the elasticity and noiselessness of a velvet pile carpet, in addition to much durability.

FLOORS. The platforms which form the separate stories of a building are habitually known by the name of Floors, and they are generally composed of the *ceiling*, the *joists*, and the *floorboards*; great varieties of construction are, however, admitted in each of these details. The various modes of executing ceilings will be discussed under PLASTERER'S WORK, and attention will in this article only be called to the parts of floors which come exclusively within the attributions of the carpenter and joiner.

Floors are either *simple*, or *single-joisted floors*; or *framed floors*. In the former, the ceiling and floor-boards are attached directly to the joists, which are made strong enough to carry the weight likely to be brought upon them, without any intermediate support. In the framed floors, a more complicated system of construction is adopted, for girders are introduced to divide the bearing, and to them are attached, as the case may be, binding-joists, bridging-joists, and ceiling-joists; the two latter of which respectively carry the floor-boards and the ceiling. It is usually considered that a single-joisted floor is, in proportion to the cubical quantity of wood it contains, stronger than a framed floor; but, as Tredgold very properly remarks, when the bearing of the joists becomes considerable, the ceilings of single-joisted floors are liable to be affected by the natural movements of the timber; and at all times it is easier to execute the works required to prevent the transmission of sound in a framed, than it is in a single-joisted, floor. [SOUND BOARDS.]

The weight a floor may have to carry must of course depend upon the purposes it is intended to fulfil. In house floors it is very rarely indeed that a greater weight than 45 lbs. per foot, superficial, can be applied, whilst in common shop and assembly-room floors, it is advisable to count upon a load equal to 80 lbs. per foot, superficial, and in bridges, upon a weight of 200 lbs. per foot; if corn or grain should be stacked upon a floor, it is even desirable to calculate upon a load of 250 lbs. on the superficial foot. Upon these data the strength of the timbers of a floor may be calculated by the formula $w = \frac{b\,d^2}{l}c$; in which w = twice the breaking weight in lbs., distributed over the whole length, or the breaking weight applied at the centre; b = the breadth in inches; d = the depth also in inches; l = the clear length of the bearing in feet; and c = the coefficient of strength of the various descriptions of wood. Tredgold gives, in his 'Elementary Principles of Carpentry,' some more general empirical formulæ for calculating the dimensions of the various details of house floors; and as they are perfectly safe, nay, rather in excess of the absolute requirements of the cases they are designed to meet, they may be unhesitatingly adopted by practical builders. The scantlings of girders he calculates from the formula (No. 1.) $b = \frac{74\,l^2}{d}$; in which b = the breadth, and d, the depth in inches, and l = the length, in feet, between the bearings. The scantlings of binders he calculates by formula (No. 2.), $b = \frac{40\,l^2}{d^3}$; in which the same numeration is preserved. The scantlings of single joists he calculates by formula (No. 3.), $d = 2{\cdot}2\left(\frac{l^2}{b}\right)^{\frac{1}{3}}$; and those of ceiling-joists by the formula (No. 4.), $d = \frac{\cdot 64\,l}{\frac{b}{3}}$. Tables calculated upon these formulæ are given in the body of the work above-quoted, pages 261 to 264.

Practically the limit for the bearings of single-joisted floors seems to be fixed at from 20 to 24 feet; for although it is possible to obtain timbers deep enough to carry the loads of floors of larger spans, yet the depth becomes so considerable as to render the use of double floors preferable, even without reference to the danger and inconvenience arising from the shrinking, or warping, of the joists. The latter inconvenience may be obviated, by the introduction of a system which is now very general in London, known by the name of *herring-bone strutting*, in which the joists are kept in their places by means of cross-struts nailed at the sides of the joists, whose rigidity and steadiness are thus greatly increased. Another practical observation is to be made with respect to single joists, namely, that they must be wide enough to afford a good hold to the floor brnds; perhaps a minimum width equal to one and a half times the thickness of the floor boards used upon them may be admitted.



A span of more than 24 feet in a double floor can rarely be accomplished with ordinary timber girders; and it therefore becomes necessary to resort to the use of Trussed, or of Cast Iron, or of Wrought Iron, Girders. Of late years the latter are almost exclusively used, on account of their greater elasticity, and of their giving considerable notice of their possible weakness. Cast iron, in fact, breaks suddenly under an excessive load, without warning; wrought iron yields gradually. The rules for calculating the strength of metal girders will be found under the head of GIRDERS; they have been derived from the researches of Tredgold, Fairbairn, Barlow, and Hodgkinson.

In France, much attention is paid to the construction of a species of fire-proof floors, in which a framework of H rails, with smaller split rod intermediate bars is formed, and the spaces are filled in with the very energetic plaster obtained by the calcination of the gypsum of the Paris basin. On the top of this artificial landing, sleeper-joists are bedded, and the floor boards are nailed to them, in the better classes of rooms; whilst in the offices, or in the attics, the tiled floors are at once bedded on the joists and filling-in materials. This kind of floor has been imitated in England, and the plaster has been replaced by cement concrete; the principle of construction remaining the same, namely, the formation of an artificial landing, bearing upon the external walls. There are great advantages in these systems of fire-proof floors; but it is to be observed that they load the walls to a dangerous extent, and that in many cases the plaster, or the concrete used, exercises a powerful lateral thrust upon the walls.

The flooring itself is, in England, usually executed of white or yellow deals, or battens; in France, it is almost invariably executed of wainscot, in narrow widths, laid either with a straight joint, or in herring-bone fashion; in Holland and Germany, the ordinary practice is to use wide timber slabs, which shrink and crack in a very disagreeable manner. The boards are usually grooved and feather-tongued, or edge-nailed, in the best descriptions of work; and occasionally, when it is desired to introduce ornamental decoration in the floors, a second layer, composed of variously coloured woods is laid upon a coarser sublayer; the upper layer is usually known under the name of Parquet flooring. The thickness of the single floor boards, or battens, in England, is usually made to range between 1 and 1¼ inches; but the batten floors are rarely more than 1¼ inch thick.

FLO'RA, in the Roman mythology, was the goddess of spring and of flowers, and the wife of Zephyr. A flamen was appointed to her service by Numa. Her temple stood near the Circus Maximus. The *Floralia* were festivals celebrated in honour of Flora, from the 28th of April to the 2nd of May. Instead of the fights of wild beasts, hares and rabbits were exhibited and chased about on those occasions; and women of loose character performed dances and mimic fights, throwing beans and chick-pease among the crowd. The Ædiles presided at these games. (Cicero 'In Verrem,' v. 14.) The ground on which the games were performed is still called Campo di Fiora; it forms one of the squares of modern Rome, and serves as a market-place. Some pretend that the Flora who bequeathed this ground to the Roman people was a mistress of Pompey, the remains of whose theatre are close by. But the floral games were instituted long before Pompey, at the beginning of the 6th century of Rome. They were no doubt originally annual games of the country people. The festival was discontinued for awhile, but was restored in B.C. 173, in consequence of the blossoms of the fruit trees having in that year been severely injured by storms. As long as they were held, the floralia were scenes of the most extravagant licentiousness. The May games and floral games of the middle ages were the direct descendants of the Roman floralia. The term ("jeux floraux") was applied to the more refined poetical assemblies and competition for prizes held at Toulouse. [CLEMENCE ISAURE, in BIOG. DIV.]

FLORIN. [MONEY.]

FLOTSAM, is such portion of the wreck of a ship and the cargo as continues floating in the water. Jetsam is where goods are cast into the sea, and there sink and remain under water; and ligan is where they are sunk in the sea, but are tied to a cork or buoy, in order that they may be found again.

These barbarous and uncouth appellations are used to distinguish goods in these circumstances from legal wreck, in order to constitute which they must come to land.

Flotsam, jetsam, and ligan belong to the crown if no owner appears to claim within a year after they are taken possession of by the persons otherwise entitled. They are accounted so far distinct from legal wreck, that by the king's grant of wreck, flotsam, jetsam, and ligan will not pass.

Wreck has been frequently granted to lords of manors as a royal franchise; but if the king's goods are wrecked, he can claim them at any time, even after a year and a day.

FLOUR; FLOUR-MILLS. Under the heading WINDMILL will be found an account of the mechanism of the windmills employed in grinding flour, raising water, &c., chiefly in the days when the steam-engine had not yet come much into use, or in districts where steam-power is not readily available. Referring to that article for a description of the ordinary mode of producing flour, we shall here treat briefly of certain modern improvements, either in the substitution of steam-power for wind-power, or in the adoption of new forms of grindstone.

In the ordinary mode of grinding wheat into flour, or any other grain into meal (flour being only one kind of meal) there are circular stones employed, each about 4½ feet in diameter; they are flat discs, placed one upon another. The lower one is fixed, while the upper one revolves horizontally on a vertical axis, with a speed of 100 to 120 revolutions per minute. The surfaces are channelled or grooved, to increase their frictional effect; and they are placed so nearly in contact that grains of corn between them are crushed to powder. Now it is found that, owing to the weight (often 14 cwt.), size, and velocity of the upper stone, the flour is much heated before it can escape from the edge of the two stones; it is overground, and is apt to clog into lumps. Millers and millwrights have long sought for a cure for this evil. Some have tried to vary the shape of the grinding surfaces of the stones; while others have sought rather to direct a cold blast of air between them, in order to keep the grain and the flour cool, to separate the grains, to allow all to be acted on equally, and to prevent clogging and pastiness. To insure some or other of these results has been the main object of numerous inventions by Corcoran, Gordon, Taylor, Bovill, Pinel, M'Lellan, Banks, Goodier, Westrupp, Spiller, Valck, Seeley, Schiele, Harwood, White, and others. To notice briefly a few plans is all that need be attempted here.

Bovill's invention comprises five different elements: a mode of driving two ranges of millstones from a central horizontal shaft by means of half-crossed straps, which pass from the horizontal shaft to riggers or pulleys on the vertical spindles of the ranges of millstones; an arrangement for drying meal and flour by means of steam and hot air, instead of kiln-drying the grain previous to grinding; a mode of applying steam to give moisture to manufactured flour, which, after grinding, is in too dry a state; an arrangement for washing grain to separate its impurities, and then drying by currents of hot air; and lastly, a mode of employing machinery in combination with millstones, having apertures covered with wire-gauze or other perforated material, in order to facilitate the passing away of the ground flour through the apertures. All these parts combine to produce a very efficient grinding apparatus.

White's apparatus comprises several new principles. While the upper stone is revolving, the rhyne or connecting piece between the driving spindle and the stone is forced upon its upper side, in such manner as to serve for a rolling or crushing bed for the preparatory crushing rollers. Immediately over this rolling surface are placed the small crushing rollers, adjustable to distance by screws. The grain to be ground passes through a hopper upon the flat rolling surface driven round by the millstone spindle. The revolution of a flat disc rolling-plate causes the two crushing rollers to turn upon their respective axes, and thus to crush the grain as it is fed between the rollers. As the grinding proceeds, the crushed grain falls off the rolling-plate, and reaches the surface of a distributing-plate. The top of this distributor is corrugated radially, to aid in the distribution of the grain. The distributor is made hollow, for the passage of cool air; it has four or five air-holes, which are horizontal curved passages; the outer ends of these holes terminate at the junction of the grinding surfaces, while the inner ends open into a central aperture in the distributor communicating with a descending trumpet-mouthed tube. Air enters by these trumpet-mouths, in consequence of the suction exerted by the chambered air-distributor; the current is strongest just where the grain is most severely acted on and requires most cooling, and then the air escapes by the five or six holes.

In Westrupp's conical mill, there is a conical revolving stone placed *beneath* a fixed stone. The upper stone is a cone, hollow beneath, and the lower one is a cone fitting into it; the two being susceptible of easy adjustment, according to the size and condition of the corn to be ground. On account of the conical form of the rubbing surfaces, the flour leaves the mill very easily. It grinds the corn more completely than an ordinary mill, leaving less farina in the bran; for the bran remains awhile after the flour is expelled, and then falls by gravity to another pair of stones, where the remaining farina is ground out of it. It has been asserted that this mill obtains one shilling's-worth more of flour from a quarter of corn than the ordinary mills, and that the flour is better in quality; but this is a statement requiring confirmation.

Schiele's anti-friction corn-mill is an application to practical purposes of a peculiar curved surface, which Mr. Schiele discovered; or rather, a concave revolving surface rubbing against a convex fixed surface, to prevent a kind of irregular friction which results from the contact of conical surfaces. The gradual variation of the curvature, in relation to the increasing distance of the parts from the centre of motion, equalises the rubbing pressure. The wear upon the stones is uniform in all parts; and it is expected by the inventor that there will be no need to re-dress the stones until actually worn down many inches equally all over.

M. Falguière, a Frenchman, has invented a mill comprising a pair of vertical stones revolving at high velocities; they weigh together less than 1 cwt., and are made small and portable for use in camps and ships. The grain is fed down from a hopper into a horizontal cast-iron pipe, with an Archimedean screw inside; the screw carries it to the other end of the pipe. The stones are fixed in a pair of frames, surrounded by a copper casing in two hinged halves. The running stone is carried upon a separate shaft driven by a band. The stones are concave at their travelling surfaces, and the grain is conveyed into this space from the tube.

The *gruaux* flour of M. D'Arblay attracts much attention on the continent of Europe, on account of the great extent to which the finest and most nutritious part of the flour is retained. Hard wheats of all kinds, especially Sicilian, Russian, and Sardinian, from the large per centage of gluten which they contain, are the best adapted for the gruaux principle of grinding. The grain is first ground in a mill; the white middlings are then separated by course sieves and re-ground; and, finally, the flour is repeatedly passed through fine silk sieves. The flour produced by this tedious and expensive process is of the very finest description, especially for *pâtes* and the most delicate bread. The average produce of flour thus obtained is only 25 per cent. the weight of the grain; therefore, it is necessarily high in price.

We may here notice a singular mode of drying grain adopted by Messrs. Kennedy and Armstrong at Lisburn, in Ireland. They employ an old shot-tower, in which perforated plates are fixed in a zigzag direction from top to bottom; hot air is admitted to the under surface of each plate, and grain falls on the upper surface. Down these plates the grain passes; and, by an ingenious contrivance, at the zigzag corners it is turned over during its passage, so as to be acted on equably. The speed of descent and the heat of the air can be regulated according to circumstances. The weight of the grain turns a discharging wheel at the bottom; and a pendulum, attached to the wheel, regulates the rapidity of the discharge of the grain, and also acts as a meter of quantity. This mode of drying grain is found to be cheap, easy, and healthy, irrespective of any particular mode of grinding the corn into flour.

An experiment in corn-grinding of a very important kind was made during the Crimean war, affording testimony which may be, and certainly ought to be, suggestive of improvements in our army and navy services. In order to lessen the difficulties in the way of supplying bread to the troops, the British government sent out to Balaklava two steamers, one fitted up with machinery for grinding corn, and the other with baking ovens. Mr. Fairbairn, the engineer, being consulted, he prepared plans and drawings of the requisite machinery. The government purchased the Bruiser and Abundance steamers; and in three months all the fittings, novel as they were, were completed. The mill was capable of grinding 20 bushels of flour per hour, even while the steamer was moving at 7 or 8 knots an hour. The steamer and the mill were both worked by the same steam-engine, made by Robert Stephenson. When the two steamers reached Balaklava, about the end of 1855 or early in 1856, the Bruiser was at once set to work as a corn-mill; it ground 24,000 lbs. per day, taking any kind of corn that happened to be procurable, and never got out of order during three months' operation. The flour produced from this weight of grain was made up into 18,000 lbs. weight of 4 lb. loaves, served out daily to the troops. So few were the interruptions in this course, that in the first three months of 1856 the mill ground 1,800,000 lbs. of corn, yielding 1,330,000 lbs. of flour (the rest being bran and waste). The total cost of the wheat and grinding the flour was about one penny per pound. It does not fall within the province of the present article to notice the arrangements of the bread-making and baking apparatus; but it may suffice to say that the Abundance baked into bread all the flour which the Bruiser could grind. The steamers and the machinery were sold at a small price when the war was over; but the lesson afforded is not likely to be lost. A competent authority has observed: "The experiment forcibly suggested the necessity of a light portable steam-engine and mill for grain being constantly attached to the camp when an army takes the field. This could be done at a very moderate cost. The whole affair need not exceed the weight of a large-sized gun, such as now accompany our armies. There is no practical difficulty in the way of introducing an engine capable of supplying newly-baked bread from an oven constructed in the smoke-box of a portable locomotive engine, mounted on wheels, and prepared with grinding apparatus at the same time." Some recent experiments on army cookery, made at Woolwich, induce a hope that corn-grinding and bread-baking vehicles will by and bye be attached as regular component items in the *matériel* of an army.

Some of the flour-mills recently constructed are establishments maintained on a very extensive scale. One, on the banks of the Thames near Blackfriars Bridge, contains 32 pairs of millstones and 16 dressing-machines. All the movements are effected by steam-power, and great ingenuity is displayed in every part of the arrangements. The Americans, also, have begun the application of machinery on a large scale to the grinding of flour, not only for home consumption, but for export to England. Some of the millers in the United States adopt a singular mode of filling the flour-sacks. A trough is suspended on an axis; and beneath one end of the trough is a pair of scales, or rather the flour-pan of a pair of scales. The flour-barrel is placed on the scale-pan; flour flows through the trough into it; and when the proper quantity has been thus precipitated, and the scale-pan and barrel have descended by their weight, a small piece of apparatus catches hold of the trough, and tilts it into the contrary direction, so that no more flour can flow through it into the barrel. The apparatus thereby effects the double purpose of filling and weighing.

The flour sold in the London market is sometimes adulterated, but not to so great an extent as some other articles of food. Dr. Normandy says that "The physical characteristics of wheat-flour of good quality are the following: It has a dull white colour, somewhat inclining to yellow. It should exhibit to the eye no trace of bran, even when pressed smooth with the hand or with a polished surface. It should have a homogeneous appearance, and should not lose more than from 6 to 12 per cent. after drying in a stove; the less it loses by drying the better it is." The adulteration of flour, when it exists, is usually made by means of potato starch, bean flour, Indian corn flour, and rice flour; these are innocuous, and the dishonesty consists mainly in selling these cheap substances at the price of good wheaten flour. Some of the adulterants, however, are less innocent; such as alum, chalk, bone-dust, and plaster.

It is not necessary to enter in this place into the subject of the flour-trade, sufficient on that matter having been given in the article Corn-Laws and Corn-Trade. The relative quantities obtained from different countries vary widely and rapidly, owing chiefly to the fluctuating richness of the harvests.

FLOWERS. A term invented by the alchemists, and still in use, to denote the light flocculent sublimates obtained by heating volatile solids in close vessels; for instance, flowers of sulphur, benzoin, and antimony.

FLUE. [House.]

FLUENTS. [Fluxions.]

FLUID. This term is applied to substances of which the parts possess perfect mobility amongst themselves, but more rigorously it depends on the relative intensities of the forces which act on the component particles of masses. In bodies of permanent form, denominated *solids*, these forces not only preserve the particles in a state of rest when undisturbed but also, on the communication of a slight disturbance relative to their mean positions, reduce them, after the lapse of a very short time, to the places they possessed before; hence arises the permanence of figure and arrangement characteristic of solid bodies. On the other hand, the gases have an elastic or expansive power, which is usually attributed to caloric, because the gaseous state is induced in all substances by the communication of a high degree of heat; the particles of gases have therefore a tendency, when external forces are removed, to fly from their places in obedience to the repulsion exercised by the parts in their vicinity; they are therefore freely movable amongst each other. But the conditions of the motion of any one particle are nevertheless limited by the condensations of the particles on which they impinge, and the rarefactions of those which they abandon, and therefore, even in a gas, the disturbance of a particle only makes it describe a curve round its mean position, and the condensations and rarefactions thence generated produce inequalities of pressure which propagate like motions in the particles in the vicinity. These motions, gradually conveyed throughout the entire mass, produce vibrations, the phenomena of sound, and, it is thought, those also of light.

This yielding to the internal forces called into play by the motion of the particles of a gas is by no means opposed to but rather implies their perfect mobility. If we diminish or increase their specific weight by an alteration of temperature, they will accordingly rise or sink amongst the myriads of particles by which they are surrounded. Yet they will not rise or sink as if in vacuo, for they still will be encumbered by the influences of the adjacent particles, and therefore their motions must suffer resistance.

But in liquids, which also come under the denomination of fluids, this alteration of density and elasticity is imperceptible in ordinary motions, from whence, in physico-mathematics, they have been generally treated as incompressible bodies; still a small alteration of specific gravity is sufficient to produce a distinct motion on the particles subject to such change. By the application of a blow-pipe to the lower part of a glass vessel containing any liquid, a current, due to the alteration of density of the particles in contact with the heated part of the glass, is generated, and there is much reason to believe that many of the permanent currents of the ocean originate from a similar cause, namely, the unequal temperature of different parts of the bottom of the sea, either from the difference of their depths, or of the conductibility of the solid strata with which the fluid is in contact.

The particles of a fluid being thus surrounded by others which are subject to external forces, such as that of gravity, undergo a pressure which is estimated by considering how great it would be if continued uniform over any surface taken as a unit. The direction of such a surface is immaterial, for the particle can only be in repose when the pressures from all quarters are equal. When fluids are inelastic this pressure is entirely due to extraneous forces, such as the weight of the superincumbent mass; but in elastic fluids, as in air, the pressure is necessarily proportional to the elasticity of the particle which supports it; and this elasticity is known to increase with the diminution of the volume compressed; such fluids therefore, under the influence of external forces, acquire variable densities in their different parts.

We reserve for the articles Hydrostatics and Hydrodynamics the principles from whence the equilibrium and motion of fluids are deduced when subject to known forces; and for the article Tides the case when those forces are the attractions of the sun and moon upon the ocean.

The equilibrium of a body floating on a fluid depends on two simple conditions; namely, that the centre of gravity of the whole body and of the displaced fluid must be in the same vertical line, and the weight of this displaced fluid must be equal to that of the body: but for the conditions of the stability of the equilibrium we refer to Metacentre.

When a body moves in a fluid it suffers a resistance depending on its velocity; and when the body is small compared with the mass in which it moves the law of resistance is nearly expressed by the square of the velocity. This hypothesis was originally formed by considering that the number of particles on which the moving body impinges in a given time is nearly proportional to its velocity: we say nearly, because the particles which have been struck form returning currents which interfere with this simple law; and, secondly, that the force with which it impinges is also as its velocity, which must be modified from the same consideration. The nature of these currents has not been yet investigated, and therefore the law of the square of the velocity is adopted generally as a first approximation, but the discovery of the true law would appear to be within the limits of calculation without aid from experiment, and is a subject worthy the attention of physical mathematicians.

The resistance of bodies only partly immersed in fluids, and having a depth bearing a sensible ratio to that of the fluids, as in barges towed along canals, is subject to laws far different from those which we have considered, for the quantity immersed is itself a function of the velocity, diminishing considerably with great velocities: thus, notwithstanding the increase of resistance due to velocity, this diminution due to less immersion permits the possibility of a minimum resistance. This important subject will be further considered in the article Hydraulics.

The term fluid has been extended to the supposed media through which the forces of electricity, galvanism, and magnetism act, but little that can be relied upon has been deduced from their supposed analogy with material fluids. [Electricity.] A surer source of calculation is found in detecting the laws of their elementary actions by experiment; and indeed this process seems to point out the most feasible methods for discovering the molecular laws even of material fluids, manifested both in their tenacity and their capillary phenomena.

Fluidity cannot be easily defined in the explicit terms of its exact causes until more is known of the true laws of the forces which govern the internal arrangement of bodies; but taking the effect, we may with Laplace say, that "mobility is the characteristic property of fluids." Hence fluidity may be rendered imperfect by the admixture of solids with fluids, as in mud, &c. The effects of fluidity become still more concealed in masses consisting of heterogeneous solids holding fluids in their pores, as in moist clays, dough, &c.; nor are they fully developed in solids which, through the action of heat, are tending to a fluid state, as in melting tallow, wax, glass, &c. In none of these cases can the laws of perfect fluids be applied; but as they belong only to states of transition, their peculiar laws do not deserve, or at least have not obtained, much consideration.

FLUIDITY. All ponderable matter exists either in the gaseous, fluid, or solid state; and most solids, when heat is applied to them, may be rendered fluid, or converted into liquids, under which circumstances mutual repulsion of particles takes the place of cohesion. The degree of heat required to produce this effect is different in different solids, but, *cæteris paribus*, it is always the same in the same solid: in many cases the transition from the solid to the fluid form is sudden, while in other instances solids pass through various degrees of liquidity before they become perfectly fluid. Of the first mode of becoming fluid ice and the metals are examples, and wax or tallow of the second.

As most solid bodies may be rendered fluid by heat, so many gaseous and fluid bodies are converted into solids by diminishing their temperature. Solid bodies in becoming fluid render latent a large quantity of heat; and on the other hand, fluid bodies in becoming solid evolve much sensible heat. The heat which is requisite to the fluid existence of a body is termed the *heat of fluidity*. These facts are proved by two simple experiments. Mix a pound of water at 32° Fahr. with a pound of water at 172°, and the resulting temperature will be the mean, or 102°. If a pound of ice at 32° be dissolved in a pound of water at 172°, the solution will not have the mean temperature of 102°, but only 32°. As, then, the pound of ice, by being rendered merely fluid, absorbs 140° of heat, so the quantity of heat which becomes sensible when a pound of water at 32° is converted into ice at 32° amounts also to 140°. The actual quantity of heat rendered latent by different fluids as they liquify depends upon the nature of the substance; thus, according to Person, the under-mentioned bodies contain the annexed quantities of heat in the latent state when rendered fluid:—

Water	142·65 Fahr.
Nitrate of Soda	113·34
Nitrate of Potash	85·26
Zinc	50·63
Silver	37·92
Tin	25·65
Cadmium	24·44
Bismuth	22.75
Sulphur	16·85
Lead	9·65
Phosphorus	9·05
Mercury	5.11

The nature of fluidity will be further considered under Heat.

FLUIDS, ELASTIC. This name may be applied to all fluids in nature, since all are in certain degrees elastic; but it belongs particularly to such as are aëriform, liquid substances possessing the property of elasticity only in a low degree. [Elasticity; Peizometer.] Among the aëriform fluids, however, those which are usually considered as permanently elastic are called *gases* and the term *elastic fluid* is frequently confined to atmospheric air, and the vapours which are produced from solids or liquids by the action of heat; these last are therefore such as may be rendered solid or liquid by reducing their temperature, or by increasing the pressure under which they exist. But the difference between these and the fluids which are called *permanently elastic* is perhaps nominal, since many of the latter, by the discoveries of Dr. Faraday, are found capable of being exhibited in a liquid form. [Gas.] This philosopher, for example, obtained carbonic acid in a liquid state from carbonate of ammonia, by subjecting it to great compression in a sealed tube, one end of which was placed in a freezing mixture. The liquor was colourless. This gas, with some others, have also been reduced to the solid form. Many of the gases, moreover, on being combined with one another and with other substances, form solids or liquids; thus, oxygen gas unites with metals and becomes solid; ammoniacal gas and hydrochloric acid gas unite and form the solid hydrochlorate of ammonia; while oxygen and hydrogen gases unite to form water.

Almost all gases are invisible; but several which are so when they exist alone, become visible on being mixed with one another. Thus, binoxide of nitrogen being mixed with atmospheric air, the combination becomes visible and of a red colour. Several gases also become visible when mixed with aqueous vapour. An augmentation of the temperature of vapour may, by producing an increased rarefaction, render it invisible; and, on the other hand, a diminution of temperature will cause such a condensation as may render visible a vapour which before was imperceptible. These effects of heat and cold upon vapour have been proposed as explanations of the apparent diminution of the mass of a comet when near the sun, and of its apparent enlargement in receding from that luminary. All elastic fluids are transparent, but different quantities of light are absorbed in passing through those of different kinds, and when the thickness of a stratum of fluid is considerable, the absorption is so great as to render an object beyond it invisible.

The elastic forces of a dry gas at a given temperature are inversely proportional to the volumes they occupy; and this law holds good also both for mixtures of elastic vapours with each other, and of vapours with gases, provided no chemical action takes place between them. Thus, different fluids of equal temperatures and equal elastic forces being introduced together in a close vessel whose capacity is equal to the sum of the volumes of the fluids separately, the fluids for a time remain separately in equilibrio; but experience shows, that gradually the fluids intermingle with one another, producing a homogeneous fluid preserving the same temperature and elastic force. It has been found also that if different fluids having equal temperatures with different elastic forces, and occupying separately equal volumes v, be mixed together in a close vessel whose capacity is v, the elastic force of the mixed fluid will be equal to the sum of the elastic forces of the separate fluids, and the temperature will remain constant. When a vapour at a given temperature is compressed by being confined within a smaller space than that which it previously occupied, part of the vapour becomes condensed, and the remainder continues to possess the elastic force due to the temperature. And again, if the volume of a quantity of vapour be increased, the vapour will expand, and, if not in contact with the liquid from which it was produced, its elastic force will be diminished; if in contact with the liquid new vapour will rise to supply the void created by the dilatation, and the elastic force will remain constant.

The temperatures at which liquids become elastic fluids by the action of caloric are very various; hydrochloric and nitric ethers boil, under the usual pressure of the atmosphere, the one at 51·9°, and the other at 185°; acetic ether boils at 165°; water boils at 212°; while mercury can be made to boil only at a temperature of 662°.

The quantity of vapour produced by heat from a liquid increases with an increase of temperature, and while in contact with the liquid its elasticity varies with its specific gravity. The elastic force of vapour is increased when the vapour is mixed with air; for if the interior of a barometer tube be moistened at the upper end with water, and air be introduced in it above the column of mercury, the tube being inserted as usual in a cistern of the latter fluid, the depression of the mercurial column in the tube by the expansion of the vapour and air, in consequence of an application of heat on the exterior, is greater than that which results from the expansion of air when dry.

The atmosphere which surrounds the earth is endowed with an elastic power; and partaking, moreover, of the earth's diurnal rotation, its particles should, by their elasticity and centrifugal force combined, recede from the earth till the whole is dissipated in space. Such is not the fact; and hence it is inferred, either that at a certain elevation above the surface of the earth the elasticity of the atmosphere is totally destroyed by the absence of caloric; or that beyond the stratum in which the centrifugal force of the particles is equal to their gravitation, there may exist, in a state of rest, an ethereal fluid occupying the whole extent of space, and preventing the atmosphere from being further expanded by its own elasticity.

Now, by mechanics, it may be found, that the distance from the surface of the earth to the stratum of the atmosphere in which the centrifugal force of the particles is equal to their gravity is about five semi-diameters of the earth, at which height the density must be inconceivably small; and since it is not necessary to suppose that the ethereal fluid beyond the atmosphere of the earth is more dense or more elastic than the atmosphere at that height, it may readily be admitted, that whatever may be the effect of such a fluid in resisting the motion of a comet, it can produce no sensible retardation of the movements of the planets.

The crepuscular light which has been observed at the cusps of Venus, and the changes which take place on the apparent discs of Mars and Jupiter, afford indications that those planets have atmospheres, though, with our instruments, such atmospheres may not be rendered sensible by their action on transmitted light. If, about a planet, an atmosphere were formed in consequence of the attraction exercised by the planet on the ethereal fluid supposed to fill all space, since that fluid may have no greater density and elastic power than the atmosphere of the earth at the height of five semi-diameters of the latter above its surface, the attraction of the planet may be incapable of rendering it sufficiently dense to produce any sensible effect in refracting light to the earth. Again, the height and the law of the variations in the density of the strata in an atmosphere which may be formed about a planet by the vapours arising from waters existing on its surface, would depend on the temperature; and this we have no means of knowing: but assuming it to be equal to the mean temperature at the surface of the earth, the height of such atmosphere would be very small compared with that of the existing atmosphere about the earth. An atmosphere of either of the kinds here indicated would serve to account for the rare occurrence of remarkable refractions in the phenomena of the immersions and emersions of Jupiter's satellites, or the occultation of stars by the moon.

For the properties of elastic fluids, see also ELASTICITY; AIR; GAS; VAPOUR; and EVAPORATION.

FLUOBORIC ACID. [FLUORINE.]

FLUORESCENCE (from fluor spar), is a term which has recently been employed to designate a phenomenon the nature of which remained till lately unknown.

It has long been known that certain substances have the property of yielding solutions which, though perfectly bright by transmitted light, exhibit a sort of coloured opalescence by reflected light, quite different from the transmitted colour. The bark of the horse-chestnut, for instance, contains such a substance, to which, on account of the property, the name *Schillerstoff* was formerly given by some German chemists. Sir David Brewster discovered that on admitting a beam of sun-light condensed by a lens into an alcoholic solution of the green colouring matter of leaves, the path of the rays in the fluid was visible as a beam of blood-red light. This phenomenon, which he designated *internal dispersion*, and which he seems to have attributed to the reflection of light from suspended particles, he has observed and studied in a great many instances, among many others in the case of a green variety of fluor spar, which appears deep blue by reflected light. This blue colour Sir David showed is not superficial, but arises from internal dispersion. ('Edinburgh Transactions,' vol. xvi., part 2, reprinted in the 'Phil. Mag.' for June, 1848.)

In the 'Philosophical Transactions,' for 1845, Sir John Herschel describes a remarkable phenomenon, which he discovered in relation to the blue colour exhibited by dilute solutions of salts of quinine. The blue colour, he found, came mainly from a narrow stratum adjacent to the surface by which the light enters the fluid, but the blue rays thus produced traverse the fluid freely. The incident light, however, after having once passed through a portion of the fluid of very moderate thickness, although apparently unchanged, has undergone some mysterious analysis, whereby it is rendered incapable of again producing a similar blue stratum in another portion of the solution on which it falls, or of causing the deep blue reflexion at the surface of the green fluor above-mentioned.

In reflecting on this peculiar analysis of light discovered by Sir Sir John Herschel, Professor Stokes was led to discover that the blue light shown by solutions of quinine is produced, not by the blue rays of the spectrum, but by the more refrangible and mostly invisible rays which are known to exist. ('Phil. Trans.' for 1852, p. 463.) The most direct mode of proving this by experiment consists in forming a pure spectrum [DISPERSION OF LIGHT], and placing in it the solution of quinine. Commencing about the middle of the violet, and extending from thence onwards far into the region of the more refrangible invisible rays, the path of the incident rays within the fluid is marked by a sky-blue light, which emanates in all directions, as if the fluid were for the time being self-luminous. The blue rays produced exhibit on analysis a continuous spectrum within certain limits. They have the properties of other blue rays of like composition, and accordingly freely traverse the fluid, which is transparent with respect to blue light. The invisible rays, however, by which the larger part of the effect is produced, are absorbed with great energy, and thus it is that the light which has traversed a moderate thickness of the fluid is unaffected when judged of merely by the eye, on account of the invisibility of the rays of which it is deprived, and yet has lost its property of producing the blue stratum in a solution of quinine. Inasmuch as the incident rays are absorbed, and in their stead there issue in all directions, from the part of the fluid in which the absorption takes place, rays of a different refrangibility, the effective portion of the incident light may be said to have *changed its refrangibility*, an expression which briefly indicates the most striking of the observed facts of the phenomenon.

This change of refrangibility, when once suggested, proved to be extremely common, and to embrace the more striking instances of internal dispersion mentioned by Sir David Brewster: among others, that of the variety of fluor spar, of which mention has already been made. When a *fluorescent* body (or one which possesses the property in question) is examined in a pure spectrum, it is found that, beginning at a point of the spectrum varying with the substance examined, and continuing from thence onwards in the direction of increasing refrangibility, the incident rays in being absorbed cause the substance to emit rays of a different refrangibility, which observation shows to be *always lower* than that of the active rays. The colour of the emitted rays depends only on their refrangibility, having no relation whatsoever to the colour of the active rays, or to the circumstance of their belonging to the visible or invisible part of the spectrum. Thus, fluorescent substances, by emitting light under the influence of the invisible rays, render the presence or absence of such rays, and in case of their presence their course, a matter of direct ocular inspection, and in this sense they may be said to render visible the invisible rays. The appearances thus produced are in many cases very striking to witness, and several remarkable effects may be produced by ordinary daylight, by the aid of absorbing media (see 'Phil. Trans.' for 1853, p. 385). It is readily shown also that glass is opaque with regard to the rays of very high refrangibility, but quartz transparent; and by using prisms and a lens in which quartz takes the place of glass, the solar spectrum is shown to extend to a distance, measured from the extreme red, more than double the length of the visible spectrum; while with the electric light a spectrum is obtained no less than six or eight times as long as the visible spectrum. ('Proceedings of the Royal Institution,' Feb. 1853.)

As to the cause of fluorescence, Professor Stokes supposes ('Phil. Trans.' for 1852, p. 548) that the incident ethereal vibrations agitate the ultimate molecules of the sensitive bodies, and that these molecules in turn became new centres of disturbance, from whence emanate in all directions ethereal undulations agreeing in their periodic times, not with the periods of the vibrations which produced the effect in the first instance, but with the periods in which the molecules are disposed to swing. This supposition entails the supposition of a certain duration in the effect, equal at least to that of a great number of vibrations; but as many hundred millions of millions of luminous vibrations take place in one second, such a duration may very well exist while the phenomenon is yet as to sense instantaneous.

M. Edmond Becquerel, who has studied so carefully the closely allied phenomenon of phosphorescence, has recently devised a very ingenious instrument, which he calls a *phosphoroscope*, adapted to the study of phosphorescence of short duration, and to the detection of a finite duration of the effect in cases of fluorescence ('Annales de Chimie,' tom. lv. p. 5). With this instrument M. Becquerel has succeeded in demonstrating, in the case of crystallised nitrate of uranium and many other substances remarkable for their powerful fluorescence, the existence of a powerful phosphorescence of short duration. Although a finite duration in the luminosity has not yet been detected in the case of any liquid, these researches go far to demonstrate experimentally that there is no definite line of demarcation between phosphorescence and fluorescence, but that fluorescence is merely phosphorescence of very short duration.

It is remarkable that in a paper published in the year 1842 ('Phil. Trans.' for 1842, p. 194), Sir John Herschel mentions an extraordinary prolongation of the spectrum when received on paper washed with tincture of turmeric, which however he supposed to be due to the visibility of the highly refrangible rays, *as such*. In a paper published in 1843 ('Annales de Chimie,' tom. ix. p. 320), M. Becquerel mentions a phenomenon which he had frequently observed in the course of his researches on phosphorescence, namely, that when a spectrum was thrown on certain papers, prepared with phosphorescent substances, the more refrangible and usually invisible part situated beyond the violet was rendered visible by the screen, but only so long as the light fell upon it. This phenomenon, he suggests, may consist in a brilliant phosphorescence of short duration; but apparently from connecting it too closely with the previously known instances of phosphorescence, he failed to perceive its full bearing, and never suspected that the blue colour exhibited for instance by a dilute solution of sulphate of quinine, a fluid whose absorbing action on the invisible rays he studied by means of photography, and whose dichroism he expressly mentions (p. 289), was actually produced by the invisible rays.

FLUORIDES. [FLUORINE.]

FLUORINE (F), a substance which, though long known in combination with other bodies, has been only lately procured in an insulated state, if indeed as much as this can be said, and its properties in a separate state are consequently very imperfectly known. It was first obtained, or at any rate supposed to be obtained, in a separate form by Baudrimont, by passing fluoride of boron over deutoxide of lead, heated to redness: the gas was received in a dry vessel. Although little is known of fluorine in an elementary condition many of its compounds have been studied. Those which it forms with the metals will, if of sufficient importance, be found described under the respective metals. The following are the chief remaining compounds of this element:

Hydrofluoric Acid (HF), a compound of fluorine and hydrogen, which was first made known by Scheele. Mr. Knight ('Phil. Mag.,' xvii., p 357) first suggested an apparatus for procuring it in a state of purity, though not of the greatest strength. The properties of this acid were minutely examined by Gay-Lussac and Thenard in 1810. ('Recherches Physico-Chimiques.') Fluor-spar, or what is more correctly termed fluoride of calcium, is to be mixed with twice its weight of strong sulphuric acid, and put into a leaden or silver retort, to which a receiver of the same metal is to be adapted, and surrounded with ice or snow mixed with salt. When a moderate heat is applied to the retort the sulphuric acid acts upon the fluoride of calcium, in a mode analogous to that in which its action is exerted upon common salt in preparing muriatic or hydrochloric acid; the results are sulphate of lime, which remains in the retort, while the fluorine of the fluoride uniting with the hydrogen of the decomposed water of the sulphuric acid forms hydrofluoric acid, which, coming over in the state of vapour, is condensed in the cooled receiver; the product is best kept in a silver bottle with a stopper of the same metal.

The properties of this acid are, that it is fluid, clear, colourless, and volatile; and when it escapes into the air, it forms with the atmospheric moisture white fumes, as hydrochloric acid does. Its vapour is extremely pungent and irritating, and it acts strongly on vegetable blues. The specific gravity of hydrofluoric acid is 1·0609, but by the gradual addition of a certain quantity of water, the density may be increased to 1·25. Its attraction for water is very great, and when dropped into it they combine with a hissing noise. The liquid acid is extremely corrosive; when a drop is allowed to fall upon the skin it produces painful sores. Until recently the concentrated acid here described was supposed to be anhydrous, but it is now known to contain water, which may be removed by the addition of anhydrous phosphoric acid, the true anhydrous acid then escapes as a colourless gas of a very irritating odour and which by means of a freezing mixture may be condensed to a colourless mobile liquid.

The reason for the necessity of distilling and keeping this acid in metallic vessels is that it acts upon and decomposes glass with great facility, on account of its great affinity for silica which the latter contains. Hence it has been rendered extensively useful for ornamental etching upon glass.

When hydrofluoric acid is brought into contact with certain metals it is decomposed, hydrogen gas being evolved, and a metallic fluoride formed: upon potassium this action is extremely energetic, and is attended with the evolution of gas and the formation of fluoride of potassium. With metallic oxides it forms a fluoride and water.

Hydrofluate of ammonia may be obtained by saturating the acid with the alkali; it is an unimportant salt, not being applied to any purpose whatever.

Fluoride of Silicon, (SiF_3) sometimes improperly termed *Fluosilicic acid*, is prepared by mixing equal quantities of fluoride of calcium and silica with three times their weight of sulphuric acid in a retort; on the application of a moderate degree of heat action takes place; and it appears that the oxygen of the silica is transferred to the calcium of the fluoride and converts it into lime, which combining with the sulphuric acid forms sulphate of lime, while the fluorine and silicon set free combine to form fluoride of silicon, which rises in the gaseous state, and is to be received in very dry air-jars filled with and inverted in mercury.

The gas thus obtained is colourless, its odour is peculiar, suffocating, and acid, and it fumes on coming into contact with the moisture of the air, but much less so than fluoboric acid gas. Its specific gravity, according to Dr. Davy, is 3·600, while Dumas makes 3·574. It suffers no change by exposure to a high temperature, and it has not been liquefied by condensation. It is absorbed and decomposed by water, forming a solution which contains a peculiar acid,—the *hydrofluosilicic* acid ($3HF, SiO_3$).

When potassium is put into this gas, it inflames and burns. When the gas is passed over iron heated to whiteness, there is formed an extremely thin coating of fluoride of iron and silicium, and the gas then passes without further alteration.

It does not decompose the alkaline carbonates when dry at common temperatures, nor is it absorbed by them, however long they may remain in contact; most hydrated oxides however absorb it without the assistance of heat.

Fluoride of silicon condenses double its volume of ammoniacal gas, and forms with it a volatile compound, which is of no importance; when it acts upon metallic oxides both are decomposed, the results being silica and metallic fluorides.

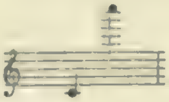
Fluoride of Boron, (BF_3) improperly termed *fluoboric acid*, was obtained by Gay-Lussac and Thenard by heating a mixture of fluor-spar, or fluoride of calcium, and vitrified boracic acid. In this operation the oxygen of the boracic acid combines with the calcium of the fluoride of calcium and converts it into oxide of calcium or lime, and the fluorine and boron then uniting form the compound in question. The properties of this gas are, that it is colourless, has a pungent odour, is deleterious to animals, and extinguishes flame. It reddens litmus paper strongly; and when bubbles escape into the air, they combine with its moisture and produce a very white dense fume. Water dissolves about 700 times its volume of this gas. The solution is strongly acid, and emits fumes, and is found to contain *hydrofluoboric acid* (HF, BF_3). This solution does not act upon glass, nor does the gas itself; but they readily decompose animal and vegetable substances. Thus, a piece of paper put into the jar of the gas over mercury is decomposed and charred as if burnt, by the abstraction of the elements of water from it, for which the gas has so powerful an affinity. When potassium is put into this gas it burns, and a brown mixture of boron and fluoride of potassium is obtained.

FLUOSILICIC ACID. [FLUORINE.]

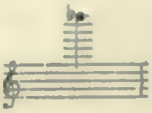
FLUTE, a well-known musical instrument, the use of which, under different forms and names, may be traced to the remotest periods of antiquity. Most of the ancient poets ascribe its invention to no less personages than gods and goddesses. Even the grave Plutarch, in his dialogue Περὶ Μουσικῆς, attributes it to Apollo. Lucretius, however, contents himself by deriving its origin from the breathing of western winds over certain reeds, and thus, he tells us, was suggested to man the rural pipe, a simple tube, which the ingenuity of later ages has improved into one of the most elegant and fascinating instruments of which art can boast. The word is said to be derived from the Latin *fluta* (lamprey), a kind of eel which has seven holes lengthways in its side, and when extended resembles a very narrow flute.

The ancient flute had some sort of mouth-piece; it was double as well as single—that is, was often composed of two tubes, both played together, and hence it has not unreasonably been inferred that the enlightened nations of antiquity possessed some knowledge of harmony. There is a figure of an ancient flute-player, or a terminal Pan, in the Third Græco-Roman Saloon of the British Museum. The flute was almost universally employed by the Greeks, Romans, &c., not only in their temples, theatres, social entertainments, and armies, but also in their funeral ceremonies. It even may be said to have accompanied their public orations, having frequently been employed for the purpose of keeping the voice up to a proper pitch. From the custom of introducing it in the last offices for the dead arose the saying, *Jam licet ad tibicines mittas* (you may now send for the flute-players), when any one was *in articulo mortis*—in the last agonies.

Of the old English flute—for the invention whereof Mersenne erroneously gives this country the credit—we will say a few words. It was not unfrequently called the *flute à bec*, from the resemblance of the mouth-piece to the beak of a bird. This mouth-piece was at the upper and wider end, and the instrument was held in the manner of the oboe and clarionet. It had seven finger-holes, no keys, and was commonly adapted either to the scale of C or F. The *flute à bec* was gradually superseded by that now in use, which long was known as the German flute—the *flute traversière*, or horizontal. This, at first simple in construction, limited in means, in length about a foot and a half, and having only one key, has by degrees been extended to twenty-seven inches, occasionally more, and has sometimes as many as a dozen keys, seldom less than six; so that every kind of music, however chromatic, within its compass, and adapted to the nature of a tube, may now be executed on this instrument. It is formed of any kind of hard wood, of ivory, and even of glass, and is divided into four joints. The scale of the concert flute is from C below the treble staff to C in the altissimo :—



Some flutes are made to go four notes lower; and an adroit player can reach the E ♭ in altissimo :—



The high notes of the flute are very effective in the orchestra, but its best, its expressive tones, are those between the low C and G in alt, comprising twelve diatonic degrees, and all the intermediate semitones. Performers on the flute, however, like those on most other instruments, strive to astonish rather than please their auditors. Tasteless, senseless execution is all-prevailing, a fact which the great majority of hearers admit, and deplore, while they nevertheless encourage the debasement of one of the most delightful of arts by patiently listening to, and often applauding, that which at best only excites some little wonder, never affords real pleasure, and commonly is the source of dissatisfaction, if not of a feeling nearly allied to disgust.

The OCTAVE FLUTE (called also the *Flauto Piccolo*, *Ottavino*, and *Flautino*, in orchestral scores) is a small instrument an octave higher than the common flute; it is shrill and piercing, and only desirable in the fullest instrumental music, and in military bands. The best of these are provided with four keys.

In the Great Exhibition of 1851, Herr Böhm, of Munich, obtained the approbation of musicians for his improvements of the flute. Mr. J. Clinton's flute is referred to in the Jury Report (Class X. A) as combining the facilities of other modern flutes, and the ordinary system of fingering, at the same time avoiding their defective parts. "In this instrument the tone and time are rendered equal by the same means that M. Böhm has adopted, namely, an equality of size and distance in the holes." It is also said to be comparatively cheap, "the mechanism being so simple that its price does not exceed that of the old eight-keyed flute."

FLUTE-STOP, on the organ, is a range of wooden pipes, tuned in unison with the diapason, and generally proves a most successful imitation of the instrument whence its name is derived.

FLUTE, FLUTINGS. [COLUMN.]

FLUX, in chemistry and metallurgy, is any substance employed to assist the reduction of ores or metallic compounds to their metallic state. In smelting the argillaceous iron ore of this country, which is a mixture of carbonate of iron, alumina, and silica, the flux employed is limestone, in such proportions as will form a slag that melts easily, so as to allow the fused iron to sink through it. When the proportion of limestone has been properly adjusted, the slag has the appearance of green bottle-glass; when, on the other hand, the slag is opaque and blue, it is a sign that a good mixture has not been made.

When copper ores are difficult to melt, fluor spar is added as a flux, which appears to promote the operation.

The fluxes made use of in assays and in chemical operations vary greatly according to the nature of the metal to be reduced and that of the substances combined with it. [ASSAYING.]

We shall mention a few of the more important fluxes employed.

Black flux is made by mixing one part of powdered nitre with two parts of powdered argol, which is the commercial name for impure cream of tartar, or bitartrate of potash: this mixture is to be gradually thrown into a red-hot earthen crucible so as to deflagrate it, taking care not to make the heat so high as to fuse the mixture.

In this case the nitric acid of the nitre is decomposed, its oxygen acts upon the carbon of the tartaric acid, carbonic acid is formed, and this uniting with the potash both of the nitre and bitartrate is converted into carbonate of potash; the whole of the carbon of the tartaric acid is not, however, so acted upon, and the excess remains mixed with the carbonate of potash in the state of finely-divided charcoal. This flux should be immediately reduced to powder and kept in a well-stopped bottle, otherwise it will become damp by the absorption of moisture, to which the carbonate of potash is subject.

This flux is doubly useful; the carbonate of potash combines with the earthy parts of the ore, such as silica and alumina, while the charcoal unites with the oxygen of the metallic oxides, and carbonic acid being formed and expelled, the metal is reduced, and melts. This flux is especially useful in the process of detecting arsenious acid and reducing it to the metallic state.

White flux is a carbonate of potash made by deflagrating equal weights of nitre and bitartrate of potash; the quantity of this last salt being smaller than that in black flux, there is no excess of charcoal furnished by tartaric acid. It appears to possess therefore no advantage over common carbonate of potash, and either of them may be employed in reducing metallic chlorides, such as that of silver, to the metallic state. White flux, or carbonate of potash, disintegrates stony matter, as alumina and silica, separates acids and sulphur from metals, and dissolves many metallic oxides; having, however, no charcoal in its composition, it does not reduce metallic oxides as the *black flux* does.

Argol, already described as an impure bitartrate of potash, powdered and mixed with the pulverised substance to be reduced, is sometimes advantageously used as a flux; owing to the intimate mixture of the charcoal and potash in this flux a good deal of potassium is evolved, and upon the reducing property of this metal the reduction of the oxides of other metals frequently depends to a considerable extent.

Charcoal alone is, in the case of pure oxides, sometimes employed as a flux; thus a crucible lined with charcoal is useful for the reduction of oxide of iron, or the oxide may be mixed with charcoal.

There are some bodies which are even more efficient than charcoal in certain cases, such as wax, fat, oil, tar, and pitch, and gum, sugar, or starch; these may be intimately mixed with the substance to be reduced, and they not only contain carbon in a form which is readily developed, but also hydrogen, which is likely to assist in the separation of the oxygen from metallic oxides.

Flint glass is sometimes, but improperly, used as a flux, for it contains much lead that may greatly interfere with the results produced.

Green bottle-glass has also been used for this purpose, but it is objectionable on account of its containing iron, and it even yields traces of silicon and aluminum to iron which was pure before being heated with it.

FLUXIONS, FLUENTS, METHOD, NOTATION, AND EARLY HISTORY. The method of fluxions assumes a distinct conception of velocity, both in the case of a uniform and variable motion. It further extends this notion of velocity or rate of increase, derived from the consideration of a moving point, to all species of magnitudes, and even to expressions which are purely numerical, as the formulæ of algebra. If one magnitude depend on another for its value, so that a change in the first produces a change in the second, and if the first be imagined to increase at a uniform and given rate, then the second will also increase or decrease, but not at a uniform rate, unless the second magnitude y be determined from the first x by an equation of the first degree, $ax \pm by \pm c = 0$. But the rate at which y increases, though varying with the values of x, can in all cases be determined; and, supposing $\dot{x}$ to be the velocity with which x increases, and $\dot{y}$ that of y, an equation can always be produced of the form

$$\dot{y} = \left\{ \begin{matrix} \text{a function of } x \text{ and } y\text{, depending on} \\ \text{the equation which connects them} \end{matrix} \right\} \times \dot{x}.$$

In this case y and x were called by Newton *flowing* quantities, and $\dot{x}$ and $\dot{y}$ were called their fluxions: conversely y and x were called the *fluents* of $\dot{y}$ and $\dot{x}$. Thus when $y = x^3$ it may be shown that $y = 3x^2\dot{x}$ and if $x = 10$, $\dot{y} = 300\,\dot{x}$, or if the number be increasing continuously, then the increasing number being 10, its cube is increasing 300 times as fast as itself. Thus while a number changes from 10 to 10·01, its cube changes from 1000 to 1003·003001, and 3·003001 is 300·3001 times as great as ·01. That this is not exactly 300 arises from the rate of increase of x^3 not being uniform when that of x is uniform. [VELOCITY.] The velocity of y being variable, may itself be considered as having a rate of change. Thus, if the velocity of a body increase uniformly, the whole velocity gained in a second may be called the velocity of the velocity, or the fluxion of the fluxion. Thus if x increase uniformly, the velocity of $\dot{x}$ is nothing or $(\dot{x})^{\cdot} = 0$, but if $y = x^3$ then $(\dot{y})^{\cdot} = 6x\,\dot{x}^2$. Newton denoted these second fluxions by $\ddot{y}$ and $\ddot{x}$. In a similar way might be determined the velocity of $\ddot{y}$, denoted by $\dddot{y}$, and so on. We cannot find that Newton proposed any symbol for the fluent of a fluxion except the enclosure of its expression; thus,

$$\boxed{3x^2\,x}\ \text{is the fluent of } 3x^2\,\dot{x}\text{, or } x^3.$$

He also in his treatise 'De Quadratura Curvarum,' used z' to stand for the fluent of z.

We now come to the history of this discovery, and of the dispute relative to the right of invention. We have already given a brief outline of the circumstances which led to the publication of the COMMERCIUM EPISTOLICUM, and we shall now add the previous and subsequent occurrences, with some quotations from authorities.

The biographers of Newton state, that about the year 1663 he began to turn his attention to the writings of Descartes and Wallis, and Newton himself testifies that he invented the method of series and fluxions in the year 1665; and that in a tract written in 1666 he had begun partially to use the notation of fluxions. In 1669 Barrow communicated to Collins the tract of Newton, afterwards published under the title of 'De Analysi per Equationes numero terminorum infinitas;' of which he afterwards says, "I am glad my friend's paper gives you so much satisfaction: his name is Mr. Newton, a fellow of our college, and very young (being but the second year Master of Arts), but of an extraordinary genius and proficiency in these things." This tract contains a method of series, and many problems solved by application of limits to differences obtained by expansion; but no direct method of fluxions. It was first published by William Jones, who had become the possessor of Collins's papers, in 1711, in a tract which is little known, having been superseded in the following year by the publication of the Commercium Epistolicum. Various letters of Newton, Collins, and others, up to the beginning of 1676, state that the first-named had invented a method by which tangents could be drawn, &c., without the necessity of freeing their equations from irrational terms. Among them is a letter from Newton to Collins, dated December 10, 1672, in which he states the fact of his discovery, with one example. This letter the committee [Commercium Epistolicum] assert to have been sent to Leibnitz, but without proof: and it has been since ascertained that nothing but an imperfect extract was sent to Leibnitz. Leibnitz desired to have this method communicated to him; and Newton, at the request of Oldenburg and Collins, wrote to the former the celebrated letters of June 13 and August 24, 1676. In the first he states the binomial theorem, and various consequences of it in combination with his method, but without giving any information as to that method. Leibnitz in a reply, also addressed to Oldenburg, speaks in the highest terms of what Newton had sent, and requests further explanation. Newton, in the second letter just mentioned, then explained how he arrived at the binomial theorem [Binomial Theorem], and gives various results of his method. He also communicated his method of fluxions and fluents *in cipher* (as was often practised at the time), if cipher it could be called, which had no method by which it could be deciphered. It consisted in placing in alphabetical order all the letters in the sentence communicated. Thus Newton gravely tells Oldenburg that his method of drawing tangents was

6 accdæ 13 eff 7 i 3 l 9 n 4 o 4 qrr 4 s 9 t 12 vx;

or, that if any one could arrange six *a s*, two *c s*, one *d*, &c., into a certain sentence, he would see the method. That sentence was, Data Æquatione quotcunque fluentes quantitates involvente fluxiones invenire, et vice versa. If Leibnitz could have taken a hint either from the preceding letters in alphabetical order, or (had he known it) in their significant arrangement, he would have deserved as much credit for his sagacity, as if he had made the invention independently. We cannot find anything in the rest of the letter which could give any such hint; and certainly Newton, who showed himself desirous to conceal the method, and knew that his letter was to come under the acute eye of Leibnitz, did not imagine that he had in any part of it betrayed his secret. This letter, of October 24, 1676, had not been sent to Leibnitz, March 5, 1677, as Collins informs Newton by letter of that date. So early as June 21, of the same year, however, Leibnitz had received that letter and written an answer to Collins, in which, without any desire of concealment, he explains the principle, notation, and use of his differential calculus: this letter was published in the 'Commercium Epistolicum.' It is of this correspondence that Newton wrote the celebrated scholium; of which, as we shall see, he was afterwards weak enough, first to deny the plain and obvious meaning, and secondly, to omit it entirely from the third edition of the 'Principia.' This scholium, very literally translated, is as follows (book ii. prop. 7, scholium).

A.D. 1687. "In letters which went between me and that most excellent geometer, G. G. Leibnitz, ten years ago, when I signified that I was in the knowledge of a method of determining maxima and minima, of drawing tangents, and the like, and when I concealed it in transposed letters involving this sentence (Data æquatione, &c., above cited), that most distinguished man wrote back that he had also fallen upon a method of the same kind, and communicated his method, which hardly differed from mine, except in his forms of words and symbols."

It will be convenient here to give Newton's subsequent explanation, given in the year 1716, taken from his remarks on Leibnitz's letter to Conti of April 9, 1716, published in 1716 in the appendix to Raphson's 'History of Fluxions.'

"He pretends that in my book of principles I allowed him the invention of the calculus differentialis, independently of my own: and that to attribute this invention to myself is contrary to my knowledge there avowed. But in the paragraph there referred unto I do not find one word to this purpose. On the contrary, I there represent that I sent notice of my method to Mr. Leibnitz before he sent notice of his method to me: and left him to make it appear that he had found his method before the date of my letter; that is, eight months[*] at the least before the date of his own. And, by referring to the letters which passed between Mr. Leibnitz and me ten years before, I left the reader to consult those letters[*] and interpret the paragraph thereby. For by those letters he would see that I wrote a tract on that method and the method of series together, five years before the writing of these letters; that is, in the year 1671. And these hints were as much as was proper in that short paragraph, it being beside the design of that book to enter into disputes about these matters."

Nothing material passed till 1684, in which Leibnitz gave his first paper on the Differential Calculus in the Leipzig Acts. In 1687 the 'Principia' was published by Newton; and Leibnitz continued to give papers on the subject of his new calculus. The Bernoullis began to cultivate the subject about the year 1691, and as they were on terms of correspondence with Leibnitz, he was the source from whence they drew, and to which they returned, additional ideas on the subject. The Marquis de l'Hôpital was employed in writing his elementary treatise (the first written), which was published in 1696. All these considered Leibnitz as their chief; and the consequence was that Dr. Wallis informs Newton, by letter of April 10, 1695, that "he had heard that his notions of fluxions passed in Holland with great applause by the name of Leibnitz's Calculus Differentialis." Accordingly, Wallis, who had just completed printing the first volume of his works (the third, which contains Newton's letters to Oldenburg, having been previously printed), inserted in the preface, as a reason for not mentioning the differential calculus, that it was Newton's method of fluxions which had been communicated to Leibnitz in the Oldenburg Letters. A review of Wallis's works, in the 'Acta Eruditorum, or Leipzig Acts,' for 1696, reminds the reader of Newton's own admission above cited. On this Newton (Raphson, supplement above cited) remarks, "Whether Mr. Leibnitz invented it after me, or had it from me, is a question of no consequence, for second inventors have no right."

In 1699 Fatio de Duillier, a Genevese, settled in England, stated in a mathematical work his conviction that Newton was the first inventor, adding that he left it to those who had seen the manuscripts and letters to say whether Leibnitz borrowed from Newton. This was the first distinct suspicion of plagiarism; and Leibnitz, who had never contested the priority of Newton's discovery, and who appeared to be quite satisfied by Newton's admission, now appears for the first time in the controversy. In a reply to Duillier (Leipzig Acts, 1700), after calling attention to Newton's scholium, he declares that when he published his method, in 1684, he knew nothing more of any method of Newton, except that the latter had written to him that he could dispense with the removal of irrational terms; and that, though on the publication of the 'Principia' he became aware how much further its author had pushed his discoveries, he did not know that Newton possessed a *calculus* (or organised method) like the differential, till the publication of Wallis's preface.

The 'Quadrature of Curves' was published by Newton in 1704, at the end of his 'Optics.' It contains a formal exposition (the first published) of the method and notation of fluxions. Some propositions had been already published by Wallis. But in all that Newton had previously allowed to be published, as well as in his early papers which have been published in our own time, he uses the language and ideas of *infinitely small quantities*. These he now rejects.

Since so great a stress was laid by the parties to the quarrel on the introduction of specific notation, we may remark that Newton himself did not very soon adopt such a course. He says that in 1666 he "sometimes used a letter with one prick for quantities involving first fluxions; and the same quantity with two pricks for quantities involving second fluxions." Even so late as 1687 he does not (in the 'Principia') give any notation for the *momenta* to which he had given a name, and (though not laying any stress on it) we doubt whether Newton would ever have systematised his notation if he had not seen the letter of Leibnitz referred to in the scholium.

A review of the above work appeared in the 'Leipzig Acts,' January, 1705, in which, after stating that the differential calculus had been explained in that work by Leibnitz, its inventor, and further by the Bernoullis, and De l'Hôpital, the author proceeds as follows: "Instead of the Leibnitian differences Newton applies and always has applied (adhibet semperque adhibuit) fluxions, which are *quam proximè* as the increments of flowing quantities generated in infinitely small times, and has used them with elegance both in his 'Principia' and in subsequent writings, just as (quemadmodum et) Fabri in his synopsis has substituted (substituit) motion for the method of Cavalieri." This was considered by Newton's friends as an imputation of plagiarism on their chief; but such a construction was always strenuously resisted by Leibnitz. On the one hand, it was declared that Newton was represented in the same light with regard to Leibnitz as Fabri to Cavalieri, by the force of "quemadmodum et;" on the other, it was replied that the distinction between separate invention and borrowing was preserved in *adhibuit* and *substituit*. We are inclined to suspect that the meaning of the writer was not very fair, though the words *semperque adhibuit* are rather in his favour. Be this as it may, the preceding sentence called forth the assertion of Keill ('Phil. Trans.,' 1708), that

---

[*] He must have known by Collins's letter that it was not three.

[*] They had not then been published, nor was it known that they were to be published.

Leibnitz had inserted Newton's method, changing its name and notation in the Leipzig Acts. The article COMMERCIUM EPISTOLICUM takes up the history at this point.

The 'Commercium Epistolicum' did not reach Leibnitz, who was at Vienna, for a considerable time. In the mean while he wrote to John Bernoulli (who had received his copy) for his opinion of the work. This the latter gave, first in a letter to Leibnitz, and afterwards (as Leibnitz asserts) in an anonymous tract published in July, 1713. But, as in this tract the author speaks in complimentary terms of John Bernoulli, it has been supposed that at least it was edited by some one else. This letter is decidedly as unfair towards Newton as the friends of the latter had been towards Leibnitz; it asserts the method of fluxions to be a plagiarism from the Differential Calculus. Keill printed a reply, and Newton and Leibnitz then appear as mutual accusers, in letters to Mr. Chamberlayne. Nothing remarkable arose out of this correspondence, which terminated in the announcement of Leibnitz that he also would prepare a 'Commercium Epistolicum.' About December, 1715, Leibnitz re-opened the matter in a letter to the Abbé Antonio Conti of Venice, then on a visit to England. He there complains of the treatment he had received, and attacks the Newtonian philosophy in general. Newton wrote a reply, February 26, 1715–16, in which he very much dwells on previous admissions made by Leibnitz. The latter, in a third letter to Conti, April 9, 1716, avows that he always believed Newton upon his word, but that, seeing him connive at accusations which he must have known to be false, it was natural that he (Leibnitz) should begin to doubt. Newton is also reminded that he had made some admissions in favour of Leibnitz (in the scholium) which he was now desirous of disavowing. This letter was not sent directly to Conti, but first to Paris, that it might be there seen and copied by a friend: on which Newton refused to send any answer, considering it as an insult that Leibnitz, though he complained of suppressions in the 'Commercium Epistolicum,' should take means to preserve evidence to the whole of his letters. But Newton circulated some remarks among his friends, which he published immediately on hearing of the death of Leibnitz, November 14, 1716. It is in this last paper that the remarkable sentence occurs which we have quoted above in connection with the scholium which it disavows. Raphson's 'History of Fluxions' being then ready for publication (its title-page bears 1715), or perhaps published, the Conti correspondence was annexed as a supplement.

The history of the controversy ends with the death of Leibnitz, and we shall conclude this article with a few additional quotations and facts which bear upon the subject.

1. The second letter of Keill (May 24, 1711) [COMMERCIUM EPISTOLICUM], on which the whole of the subsequent dispute arose, was in substance the statement of Newton himself. In the minutes of the Royal Society, April 5, 1711, it is stated that "the president gave a short account of the matter, with the particular time of his first mentioning or discovering his invention, referring to some letters published by Dr. Wallis: upon which Mr. Keill was desired to draw up an account of the matter in dispute, and set it in a just light." The letter in question was the consequence, which was read at the meeting of the 24th of May (its date).

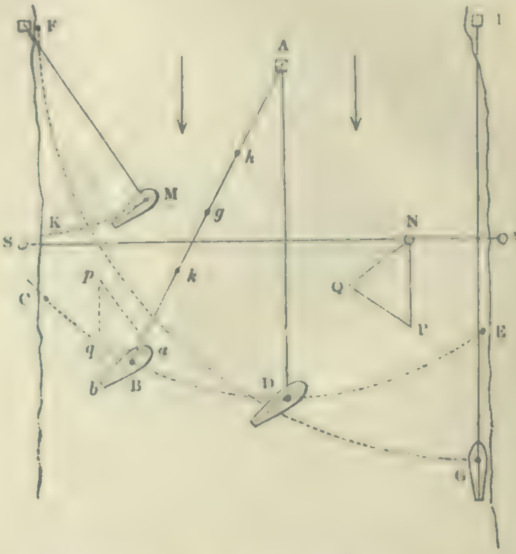
2. The original committee consisted of Dr. Arbuthnot, Mr. Hill, Dr. Halley, Mr. Jones, Mr. Machin, and Mr. Burnet. This is what Newton has been supposed to call "a numerous committee of gentlemen *of several nations*:" and singularly enough, no writer on the other side has ever noted this apparent unfairness. But it has lately been discovered that Newton was right. During the investigation there were added to the committee, Robarts, Aston, Brook Taylor, *Bonet*, the Prussian minister, and *De Moivre*. The names of the committee were not published with the 'Commercium Epistolicum.'

3. So far from the committee considering themselves as in any judicial capacity, it appears, from a letter of Burnet above-named to John Bernoulli (which the latter sent to Leibnitz, and the extract is in the published correspondence of the two), that the Royal Society was busy proving by original letters that Leibnitz might have seen the method of fluxions in the correspondence of Oldenburg, &c.

There was throughout the whole dispute a confusion between the knowledge of fluxions or differentials and that of a *calculus* of fluxions or differentials, that is, a digested method with general rules. If the dispute could be revived at the present time, it would be on entirely different grounds: but of course, in describing the controversy as it existed, we need only consider those points which were put in issue by the parties themselves.

FLYING BRIDGE. This consists usually of a boat or other vessel which, being attached by a rope to a buoy, moored in the middle of a river, is made, by the action of the current, to move across on an arc of a circle of which the buoy is the centre. On large rivers, at places where the communications across them are very frequent, such bridges will probably, in future, be superseded by steam-vessels; but, for temporary purposes, and particularly to facilitate military operations in countries where steam navigation is not in use, they may be of the highest importance.

Let A be a buoy securely anchored in the middle of a river, and B a boat to which, at a point about one-third of the vessel's length from the head, is attached one end of the cable or chain B A: then $p\,b$ indicating the direction of the current, if the keel $a\,b$ of the boat be inclined to that direction in any angle as $p\,b\,a$, the pressure of the water against one side of the boat being resolved in a direction $q\,a$ perpendicular to $p\,b$, or across the river, will cause the boat to describe the arc C D E, whose centre is A. As far as the point D, in the middle of the river, the boat descends, but afterwards it ascends obliquely against the current; for while its keel is kept by the rudder in a position nearly parallel to $b\,a$, the force parallel to $q\,a$ continues to act and impel the boat towards E. If f represent the direct force of the current, and θ the angle $p\,b\,a$, the force perpendicular to $p\,b$ will be expressed by $f \sin^2\theta \cos\theta$; and this will be a maximum when $\theta = 54^\circ 44'$. It is evident that by increasing the length of the rope A B, the length of the arc between C and E will be diminished; the retardation arising from the action of the current, in ascending from the middle of the river to E, will also be less: the length of the rope or chain should, in fact, be such that the arc C D E may not exceed a quarter of the circumference of the circle; and when, for this purpose, the length is very great, it must be supported as at g, h, and k, on moveable buoys or small boats.



A flying bridge sometimes consists of a simple flat-bottomed vessel, having a mast fixed to one of its sides in the middle of its length. The cable passes through a block at the mast head, and is attached at one end to the opposite side of the vessel, the other end being made fast to the buoy. Two ropes connected with the cable lead one to the head and the other to the stern of the vessel; and, by pulling on one of these, the other being let go, the vessel is placed in a position oblique to the current: this position is retained by means of a steering oar aided by a current-board which may be let down into the water at the head or stern as the case may require.

In a rapid current it may be impossible to make the boat B move up the ascending arc D E; in which case a boat at F, by means of a cable made fast at H on the opposite bank, may be allowed to describe the descending arc F G. On setting out from F, the boat takes with her a coil of rope, of which one end is attached to a fixed object near that place; then, on arriving at G, the boat is drawn up along the bank to H; and by the rope is hauled across the river to F, from whence it set out. Again, a rope being made fast to an object near F, a boat may be steered obliquely from some point as K, till she comes to a part, as M, of the river at which the current acts strongly upon her; then letting go the rope and, by the rudder or steering oar, keeping the boat's keel at a proper inclination to the direction of the current, the resolved force of the water will impel the boat to some point, as G, on the opposite bank.

When the river is too wide for a boat to swing over in a single arc, two buoys may be moored in a direction across the river, at equal distances from the banks and from each other, and two boats connected with them by ropes may be impelled in circular arcs, one extending over the first half of the breadth of the river, and the other over the second: a raft being moored in the middle facilitates the transference of the passengers, &c., from one boat to the other; or, without the raft, one boat, on arriving in the middle of the river, may transfer its passengers immediately to that which is to describe the other half of the breadth.

A triangular raft N P Q having its front, as N P, parallel to the direction of the current, and being connected by a ring at N, with a rope S V stretched tightly across the river, may, by a resolved force of the current on N Q, be impelled directly to the opposite bank; and, on reversing its position so that P may be connected by a ring with the rope S V, the raft may be impelled across in a contrary direction. A boat running by a ring at one end, on S V, may, by being kept in a position corresponding to that of the line N Q, in like manner be *sheered* across the river.

On broad rivers, and when objects of great bulk and weight, as horses, carriages, or artillery, are to be conveyed across, two boats or barges placed in parallel positions, and carrying a platform extending between their exterior gunwales, are employed: the bay or interval between the vessels is as wide as is consistent with the strength of the platform, in order that as much as possible of the current may act against a side of the lower vessel. The vessels are made narrow and deep, and each is provided with a mast, which may be from twenty to thirty feet in height; these are connected together at ten or fifteen feet from the platform by two horizontal beams, one above the other, and between them is a block of wood which is capable of sliding from one mast to the other. The cable or chain is made to pass through a perforation in the sliding piece, and the latter is placed contiguously to either mast, according to the direction in which the vessels are to move. A drawbridge is constructed on each side of the platform, and one of them is let down to form a passage when the vessels arrive at the landing-place on either side of the river. Each vessel has a rudder, and the tillers are connected by a bar, in order that one man may be able to turn both.

For ample details concerning the subject of this article, see Sir Howard Douglas on 'Military Bridges.'

FLYING SAP, is the sap formed by placing and filling several gabions at the same time, and not in succession as in the usual method employed in making the second parallel in the attack of a fortress.

FO, pronounced by the Chinese Fŭh, is the name by which Buddha is worshipped in China. According to the Chinese authorities quoted in Dr. Morrison's 'Chinese Dictionary' (vol. i. part i. pp. 92, 93), the religion of Fo was introduced into China in the seventh year of the reign of the Emperor Ming, about A.D. 50. Though the Chinese government has usually discountenanced, and at some periods persecuted, the followers of Fo, they have always been very numerous; yet Sir J. F. Davis remarks, in his work on the Chinese (vol. ii. p. 94), that, "the present condition in China of the religion of Fŏ is very far from flourishing; and the extensive and magnificent establishments which have been founded in former times are evidently in a state of dilapidation and decay. It is rarely that one meets with any of their nine or seven-storied pagodas in tolerable repair, though one or two of these striking and elegant objects occur in almost every landscape. Between Macao and Canton there are no less than four or five nine-storied pagodas on elevated points by the river-side, and every one of them is in a state of ruin." [Buddha.]

FOCUS, Geometry. [Ellipse; Hyperbola; Parabola.]

FOCUS, a Latin word signifying a *hearth* or *fire-place*, used in optics to denote the point at or near which the rays of light are collected by a lens or mirror. Its distance from the lens or mirror is called the *focal length*. [Lens; Mirror.]

FOG. [Mist.]

FOG SIGNALS. The blowing of a horn, the ringing of a bell, the beating of a drum or gong or empty cask, the firing of a gun,—in short, any uncouth noise made on board a ship to warn others of her presence, is in a fog a means of safety. The Admiralty have rules for the government of a fleet of men of war in thick weather, such as occasional firing or ringing of a bell to indicate what tack a ship is upon, &c.; but little has been done for single ships of the merchant service on this important subject beyond certain regulations for the use of light-houses and light-vessels, although every provision was made in the Merchant Shipping Act of 1854, for the enforcing of such regulations as might issue from authority. Difficulties evidently beset the question, as the safe passage of a ship in foggy weather through our crowded maritime highways must depend so much on individual precaution.

As the principal commerce of the kingdom is becoming more and more carried on by steamers, and their "whistles" are a powerful and characteristic mode of warning, it might be well to organise a few signals for general use, after the following manner.

Let the mark "—" represent, on paper, a sound from the steam whistle, lasting while a person could leisurely count *four*, and the mark "⌣" indicate another sound from the whistle, enduring while a person could leisurely count *two*.

It being in a fog so important to know *in what direction a steamer is coming or proceeding*, the following eight signals would form a complete code, which might moreover, from their extreme simplicity, be used either in a dark night or in hazy weather at any time.

If a vessel is standing towards the North, let her course be represented by . . } —
If North-East " " . . — ⌣ ⌣
If North-West " " . . . ⌣ — ⌣
If East " " . . ⌣ ⌣
If South " " . . . ⌣ —
If South-East " " . . ⌣ ⌣ —
If South-West " " . . . — — ⌣
If West " " . . — ⌣

As every sailing-vessel is supposed to carry a "fog horn," the above signals so easily made on it, or on a bugle, or with a common whistle, or even with the mouth (on an emergency), would in many cases probably prevent collision [Collisions at Sea]. And further, if a vessel be on the starboard tack, close hauled, a prolonged blow would announce it, and if close hauled on the port tack, a few short repeated sounds of any sort would give sufficient notice: while a vessel at anchor might make any *beating* sound.

But all precautions taken on board ship in certain cases will prove useless unless means be taken to give sounds from the shore. The humane but partial and voluntary custom in some parts, of ringing a village church bell on a coast in thick weather, if rendered compulsory, —or the sounding of a bell at certain conveniently situated coast-guard stations along the shore,—would not only alleviate the dangers which at present threaten seamen, but it would be a boon to boatmen and fishermen. For instance, three long sounds of equal length might always be used to indicate *the shore*.

An excellent fog-horn has recently been introduced from the United States.

Fog-signals, made with an explosive material, are also used on railroads. They are placed on the rail; the engine-wheel on passing over it causes it to explode with a noise calculated to announce the approach of the train to a considerable distance.

FOIL, is a very thin sheet of metal, made usually for placing beneath artificial gems to heighten their brilliancy. Foils are made of tin, copper, tinned copper, or silvered copper—the last for the best work. They are left white for imitative diamonds, but are coloured for imitative rubies, sapphires, &c. The best white foil is made by coating a plate of copper with a layer of silver, and then rolling it into sheets in the flatting mill. The coloured foils are prepared by coating the white foil with coloured varnish. The principal colours used by artists are employed, mixed with mastic, spirit, and drying oil, to form the coloured varnishes. The following are examples:—amethyst foil, lake and Prussian blue finely ground in drying oil; sapphire foil, Prussian blue and drying oil; garnet foil, dragon's blood and rectified spirit; emerald foil, pale shellac, alcohol, and acetate of copper; ruby foil, lake, isinglass, and shellac; topaz foil, turmeric, annatto, and shellac.

Sheet lead, so extremely thin as to resemble foil, is employed as a lining for tea-chests. Mr. Wimshurst, one of the managers of the Assam Tea Company, invented, in 1858, a very peculiar method of producing this foil. It is said that England sells no less than 4000 tons of lead annually to the Chinese, chiefly to be made up into foil for lining their tea-chests; this they do rather clumsily. The Assam Company paid from 2000*l*. to 3000*l*. a year for lead-foil made on the old method of rolling; but Mr. Wimshurst has effected a great saving in this item by the adoption of his new method. He makes a cylinder of lead, by casting in a mould having a mandril or core in the centre; the mould opens by a hinge into two halves, and liberates the metal. A knife or cutter, as long as the cylinder, is gradually brought up to it, and shaves the surface. The cylinder rotates slowly while being thus cut. The mechanical arrangement is such that the cutting-blade advances gradually towards the axis of the cylinder, and the rate of this advance determines the thickness of the film. The film is received on a collecting spindle, which can be removed with the coil upon it. The cutting-machine acts equally well on a cylinder of tin or one of lead, or of a combination of the two metals.

FOLK-MOTE, or FOLK-GEMOTE, literally a meeting of the people; an assembly under the Anglo-Saxon government, respecting the nature of which some of our antiquaries have differed. Sir F. Palgrave believes that it existed in Britain before the establishment of the Saxons. Somner, in his 'Anglo-Saxon Dictionary,' calls it a general assembly of the people for considering and ordering matters of the Commonwealth. So the laws of King Edward the Confessor, "Folcmote, *i.e.*, vocatio et congregatio populorum et gentium omnium, quia ibi omnes convenire debent, et universi qui sub protectione et pace Domini Regis degunt." The continuation of this statute of Edward the Confessor expressly directs that the meeting of the Folcmote should be held once in the year upon the 1st of May. "Statutum est enim quod ibi debent populi omnes, &c., semel in anno scilicet convenire, scilicet in capite Kal. Maii." (Wilk., 'Leg. Anglo-Sax.,' p. 204.)

Brady, in his 'Introduction to Old English History,' Gloss. p. 47, is entirely mistaken when he speaks of it as an inferior ordinary court, held once a month. This was the Hundred Court. The Folk-mote and Shire-mote (or general meeting of a county) were synonymous. (Wilk. ut supr. Gloss. p. 404.) According to Sir F. Palgrave, the Folk-mote was a representative assembly to which the various districts sent their sheriff (gerefa) and four men. It certainly possessed judicial powers, of which he gives examples ('Rise and Progress of the English Commonwealth'); and jurors appear in many instances to have been selected from among the representatives attending the Folk-mote. The Folk-mote, indeed, appears to have had nearly the same constitution, with powers, limited by the locality it represented, as the Witenagemote; to which frequently the same representatives were sent as attended the Folk-mote.

In later times a Folk-mote, according to Stow, among the citizens of London, meant a meeting of themselves. Fabyan, in his 'Chronicles' (edit. 1811, p. 344), mentions a court of folk-mote held at Paul's Cross in 1256; and another assembled by command of Henry III. (ibid. p. 345), "where the king, according to the former ordinances made, axed licence of the commonalty of the city to pass the sea."

FOMENTATIONS are liquid applications, generally of a warm temperature, placed in contact with a limited portion of the body, to mitigate or remove disease of the part, or of the neighbouring organs. They differ from partial or local baths, chiefly in the greater length of time which they are kept applied. Flannel cloths, or other substances, such as the spongio-piline, fit to retain heat and moisture, are commonly employed. To enable these substances to retain the heat still longer, they are often covered externally with oiled silk. It is proper to renew the application before the cloths begin to give a feeling of coldness. The liquids used are of various kinds, sometimes pure water; at other times medicated; they are termed emollient when charged with mucilaginous principles, such as mallows, and sedative or anodyne when they contain a narcotic principle, such as poppy heads.

FONT, the vessel placed in a church to contain the water employed in baptism. The form of the font is evidently derived from that of the larger Roman stone vases, but few if any of the fonts now found in churches are of a date earlier than what in architecture is known as the Romanesque period. In our own country there are a great many fonts, curious both for their antiquity and their architectural design. One or two are, on questionable grounds, attributed to the Saxon period; but those respecting which there is no difference of opinion range from the Norman period to the decline of Gothic architecture.

What may be called the normal form of a font is that of a cup or bowl hollowed out for water, and supported on a thick solid stem. The exterior of the bowl is in the older examples round, or square, but in the later most commonly octagonal; and the sides and stem are often highly enriched with sculptured figures, and occasionally traces of colour and gilding still remain, as at Gorleston and Blythborough, Suffolk, and Gresham, Norfolk. In many instances, a flight of steps forms a base for the stem; and in fonts of the Perpendicular period, even the steps are carved with panels, having quatrefoils and rosettes sunk within them. From about the middle of the 13th century, when by a rescript of the Archbishop of Canterbury fonts were required to be covered and locked, the lids of fonts began to acquire an ornamental character equally with the fonts themselves. At first they were merely plain covers with padlocks, but eventually (though probably not before the middle of the 15th century) they assumed a pyramidal or spire-like form, richly carved with a profusion of shafts, buttresses, and tracery, piled up to the apex. Covers of this kind still remain at Castleacre and North Walsingham churches, Norfolk; Ewelme, Oxfordshire; Thaxted, Essex, and elsewhere.

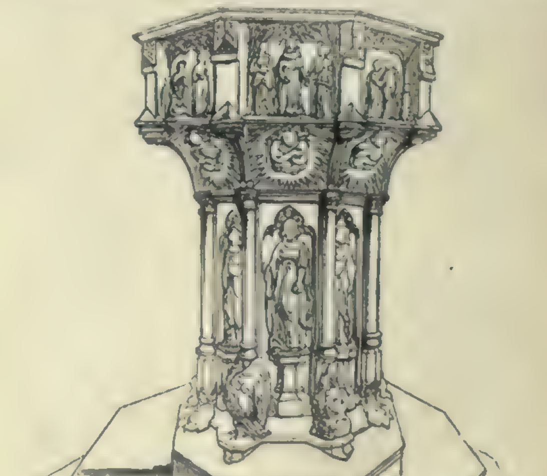
The more ancient fonts are generally very large; the basin being sufficiently capacious to permit of the baptism of the infant by immersion. As a rule they are made of stone, and almost always from a single block; but some leaden fonts of Norman, as well as of later date, are still extant both in this country and in France: in the latter country a few remain of copper or bronze. Fonts were mostly placed in the western end of the nave, near the entrance of the church; but sometimes in a portion of the church separated from the body of the building by walls or a screen, or entirely detached from it. Of these baptisteries as they were called [BAPTISTERY], examples occur at Canterbury Cathedral; Luton, Bedfordshire; Cranbrook, Kent; and Menacuddle, St. Austel, Cornwall; but more perfect examples may be found in some recent churches erected in conformity with strict "ecclesiological" principles; as All Saints, Margaret-street, London, where the font (which has a carved cover of the kind described above), is enclosed in a rich baptistery, which is shut off from the nave by low walls, though under the same roof; and at All Souls' church, Halifax, where a baptistery is formed in the basement of the tower, which stands at the north-west angle of the church.

Fonts of Norman date are nearly always large and massive; the basin is usually round or square, but some occur which have been rendered octagonal by chamfering off the angles of the square blocks, as at Drayton church, Norfolk. They are supported on a very thick stem, but in some of the largest there are also smaller shafts placed under the angles of the basin, as at Lincoln cathedral; Ifley church, Oxfordshire; South church, Hayling Island, Hampshire, &c. Norman fonts are frequently sculptured with rude bassi-relievi, of the Crucifixion or Baptism of Christ, or some other typical subject, figures of the apostles, saints, grotesque figures, scroll-work, &c. Porchester church, Hants, has a very ancient circular font, resembling in character the puteal, or circular stone-mouth of the well in the atrium of a Roman house: it is decorated with intersecting arches on columns, with a frieze of foliage and figures above. At Coleshill, Warwickshire, is a Norman font, of which the basin is a mere cylinder, but elaborately sculptured outside with the Crucifixion (enclosed within a circle), the evangelists, &c., and supported on an enormously thick stem. A handsome circular font richly covered with scroll-work occurs at Great Shefford church, Berks; at Monks Risborough, Buckinghamshire, the circular basin is fluted. Most Norman fonts are of stone, but some occur of lead. One of the most remarkable of these is in Dorchester church, Oxon. The bowl is of cast lead, of 1 foot 10½ inches internal diameter, 2 feet 2 inches external, and 1 foot deep. Around the outside are eleven seated figures under semicircular arches, representing, probably, the Apostles—Judas being omitted. The pedestal is of stone and more modern. A leaden font of very beautiful workmanship is in the chapel of Llancourt, on the Wye. Fonts of the same date in Normandy, are almost exactly similar in style, but somewhat richer and more refined in finish; showing, not merely similarity of origin, but supporting the probability of their being executed by the same workmen, or workmen trained in the same school.

Fonts of the First Pointed, or Early English date, are like those of the preceding period, circular and square, but they are likewise not seldom octagonal. In general character they greatly resemble the Norman, but they differ from them in being somewhat less massive, and more finished in style; they have sometimes arcaded-work, sometimes trefoils on the bowls, with slender shafts dividing the panels, and almost always detached supporting shafting, as well as a thick central stem.

In the Second Pointed, or Decorated Style, the fonts are finer in design than the earlier examples, but less refined in execution than might be expected from the superiority of the buildings of this period. The basins are now usually octagonal, but occasionally they are hexagonal, as at Rolvenden, Kent, and Drayton Parsloe, Buckinghamshire. Fonts of this period are characterised by the flowing tracery of the panels, engaged shafts, highly enriched ornamentation, diapered panels, and occasionally elegant sculpture. A good example of this style occurs in the church of All Saints, Norwich.

In the Perpendicular, or Third Pointed Style, the form is almost invariably octagonal. Occasionally figures of men or animals are introduced as apparent supporters to the bowl, as at St. Martin's, Oxford, where supporting figures are placed within recesses formed by buttresses at the angles of the stem; and at St. John's, Norwich, where lions are similarly placed. The ornamentation is now much more rich, becoming more and more florid in the later examples, and at last erring greatly on the side of excess of decoration, as in the otherwise fine font at Walsoken, Norfolk. On the panels of the basin foliated circles or quatrefoils frequently inclose roses or heraldic shields. The stem, where single, is often octagonal and panelled. Statuettes and bassi-relievi, sometimes very beautifully executed, occur in the costlier examples, both within niches on the panels of the basin, and around the stem. A very beautiful example of a Perpendicular font of the best period occurs at East Dereham Church, Norfolk, of which we give an engraving. The lofty pyramidal font-covers spoken of above, are chiefly of this period—the famous one at Ewelme, Oxford, which is 10 feet 6 inches high, is a characteristic example.



Font in East Dereham Church, Norfolk, from an original drawing made by Mr. W. B. Clarke, architect, in 1834.

From the decline of Gothic architecture little attention was given to fonts in this country; and not only were no new ones of any artistic pretension executed, but the old ones were neglected, and often applied to the most unworthy uses. Since the revival of Gothic architecture, however, many fonts have been executed of a very costly kind, and exhibiting great imitative skill, if not much originality of design.

Simpson's 'Series of Baptismal Fonts,' and Paley's 'Illustrations of Baptismal Fonts,' furnish descriptions and engravings of numerous English fonts of the several periods, and the latter work gives also careful admeasurements of each example: the 'Archæologia,' the 'Archæological Journals,' and the local histories, will supply many additional instances. Sufficient examples and descriptions (for the purpose of comparison) of French fonts, will probably be found in M. A. De Caumont's 'Cours d'Antiquités Monumental,' vol. vi., and 'Atlas,' Paris, 1841; and his 'Rudiment d'Archéologie—Architecture religieuse,' Par. 1854.

FOOD. All organised bodies are nourished by he introduction into their internal structures of materials from without. Such materials are called indifferently aliments or food, and are fitted to supply and maintain the fluid and solid matter of the body. For this purpose they must either be soluble naturally, out of the body in common menstrua such as water, or capable of being dissolved by the digestive principle of the stomach. However diversified the articles employed may be in external appearance or chemical composition, they are reduced by the action of the organs of digestion into a fluid (chyle) [DIGESTION, in NAT. HIST. DIV.] of homogeneous character, which is reconverted into solids and fluids of different natures by the influence of the powers of assimilation. Before undergoing this second change, they must be brought into the state of arterial blood, and so form a part of the circulating fluids of the body. Substances which are incapable of undergoing these successive changes cannot be considered as articles of food, or capable of imparting nourishment to the frame. There are however various articles which, although incapable by themselves of nourishing, appear, when taken in conjunction with other articles, to contribute essentially to nutrition. But even of a substance unquestionably nutritious, the whole mass is never completely nutritive, that is, capable of being entirely assimilated; some portion of it merely giving it bulk, or being of a nature calculated to make certain impressions on the organs of digestion, and to stimulate them to those actions which conduce to the exercise of the function of digestion, such as the *tannin* of our vegetable food, salt and other condiments.

Those substances which have previously been endowed with life can alone be considered as affording nutriment to animals of a high degree of organisation, such as man, of whose aliment we here mean to treat. For a practical view of the subject, it may be divided into two heads, namely, the substantials and the accessories; the first comprising the real materials or sources of nourishment; the second, condiments, &c., which either render the food more grateful to the palate, or by a vital or chemical action on the organs of taste and the stomach, promote its digestion.

It is customary to distinguish the articles of food into solid and fluid, or meats and drinks, and into animal and vegetable. But the former is merely a distinction of convenience, and does not extend to any ultimate difference in the nature of the material, but only to the manner in which they are respectively treated by the organs of digestion; while the latter is only important in a medical point of view, as relates to the amount of nutriment in a given quantity of food, and the impression which the two kinds of food make upon the system generally. "Specific differences are distinguishable in the chyme at least, if not in the chyle, according as the food from which it is formed has consisted of vegetable or animal matter, and according as it has contained fatty or oily substances, or been destitute of them." Nevertheless as those substances alone contribute to the nourishment of the body by being assimilated by it which can be resolved into *their organic molecules*, and as these are only found in the proximate principles of animals and vegetables, of which principles none perhaps are exclusively animal, it seems most advantageous to treat at the outset of the principles, without reference to the source whence derived. The molecules can only be liberated by being diffused through some fluid, and therefore it matters not whether they be brought into such a condition by external agency or by the apparatus with which the higher animals are furnished, namely, the teeth, stomach, &c. To a fluid state they must be brought before they can pass the fine strainers of the alimentary canal. The resolution of the materials of food into their organic molecules is the real office of the digestive organs, while exercising that function within healthy limits; the resolution of the proximate principles into their elementary or ultimate principles, when various gases are evolved, is a morbid or diseased action of these organs.

The proximate principles of alimentary substances consist sometimes of three, sometimes of four elementary or constituent principles. Those which consist of three are of most frequent occurrence in the vegetable kingdom; those which consist of four are of most frequent occurrence in the animal kingdom. Where the elements are three only they are generally oxygen, hydrogen, and carbon; where four, oxygen, hydrogen, carbon, and nitrogen, or azote. The predominance of carbon is the characteristic of vegetable matter; the predominance of nitrogen the characteristic of animal matter. Wherever nitrogen is absent in animal matters the substance approximates, or is analogous to, vegetable matter, such as animal fats, which closely resemble vegetable oils. Animals which are decidedly carnivorous do not prosper if kept long on food destitute of azote; but man, whose dwelling-place is under different climates, can dispense with an azotised diet better in some parts of the world than in others, for instance, better in tropical countries than near the poles. The pilgrims and attendants on the caravans in their journeys across the deserts of Africa can subsist for a length of time on gum, which does not contain azote. Majendie, who carefully investigated the subject, concludes from his experiments—1st, That animals derive the azote which enters into their composition entirely from their food, and hence, that no animal can live for a considerable time on food entirely destitute of azote. 2nd, That animals, even those naturally carnivorous, can live a certain time upon food entirely destitute of azote, in consequence of which the excretions of those naturally carnivorous become altered, throwing off less azote than when they are fed on animal food, and acquiring the properties which these excretions have in animals whose food contains a very small proportion of azote. 3rd, That vegetable and animal substances destitute of azote are highly nutritious, provided at the same time azote can be supplied from some other aliment containing it, though in small proportion. It seems however that vegetable aliments acquire an accession of azote in the digestive organs, though probably at the expense of some part of the system. Admitting the general correctness of Majendie's views, alimentary substances may be divided into three classes:

I. Those which contain azote, carbon, oxygen, and hydrogen.
II. Those which contain carbon, hydrogen, and oxygen.
III. Those which contain neither azote nor carbon.

The first class naturally demands the greatest share of attention, because "the aliments which contain azote correspond with animal substances in general, and are calculated to repair the waste of our solids and fluids without great alteration or effort in the digesting organs. All the immediate principles of this class are not however equally digestible, or possessed of the same properties." It is necessary therefore to say a few words on the leading forms or states in which azotised principles occur.

Fibrin: this and other terms are retained here, though not in strict accordance with the present chemical phraseology with respect to food and its constituents, because these having been long in use are better known to unscientific readers. The modern views and phrases are all given under the Art. FOOD, in NAT. HIST. DIV. Animal *fibrine*, animal *albumen*, and animal *caseine*, constitute the chief animal proteinaceous principles, that is, compounds of protein and sulphur, and in the two former of phosphorus also. [PROTEIN.]

1. *Fibrin.*—This is found in greatest abundance in the animal kingdom, constituting the principal part of the muscular fibre of animals, and no inconsiderable portion of the blood, when by rest that fluid is coagulated. It has been thought to exist in some of the constituents of the vegetable kingdom, particularly in the juice of the fruit of the Carica Papaya, or papaw-tree, and in certain other plants with a milky juice, such as the Palo de Vaca, Cow-tree (Galactodendron utile) of South America, and some fungi, or mushrooms. The identity of the principle found in these vegetables with animal fibrin has been questioned by some recent chemists. Dr. Thomson considers the principle of the cow-tree distinct, and terms it galactin, while Gmelin terms that of the others emulsin, which he considers analogous to gluten.

Fibrin constitutes the chief part of the solid matter of the muscles of animals, particularly of those which are old and have dark-coloured dry flesh: it is that portion which remains in the form of fibres after all the soluble matters have been removed from the flesh of animals by long boiling. It is insoluble in cold water, is corrugated by long boiling in water, is insoluble in alcohol, but strong acetic acid causes it to swell considerably, rendering it transparent like cartilage, in which state it may be dissolved, or, at least, diffused through water by long boiling.

The flesh of animals is divided into white and coloured, and indeed it differs in the same animal at different ages, having different accompanying constituent principles at different periods of life. Thus in the calf the muscles are white, or only pinkish; in the ox they are deep red; in the first state much gelatin and little of ozmazome is present; hence the gravy of veal easily gelatinises, while that of beef rarely does so.

Fibrin is in general more tender, that is, more easily digested, because the force of aggregation is more easily overcome by the powers of the stomach in middle-aged than in old animals, and in the flesh of the female than that of the male, unless the males have been castrated when young.

Albumen is another important constituent of animal bodies, but of more sparing occurrence in vegetable substances. In animal substances it occurs in two states, fluid and coagulated. The most perfect examples of it in the former state are the white of eggs, which is an alkaline solution of albumen, and the blood, which is likewise probably an alkaline solution of albumen. Coagulated albumen constitutes cartilage, horn, hair, and the nails or hoofs of animals. It forms the chief constituent part of oysters, muscles, snails, &c. Milk is an albuminous fluid.

At the temperature of 165° Fahr. albumen is coagulated, and it is likewise solidified by many acids, such as that of the gastric juice (in the form of rennet), and by some metallic salts. Milk, though coagulated by acids, is not so by boiling.

Albumen is likewise found in the green feculæ of plants in general, and in some vegetables in very considerable quantity, such as the fruit of the *Hibiscus esculentus*, or *Ochro*, and the bark of the *Ulmus campestris*, or elm. The former is used in Sicily to thicken soups, and both are used in the West Indies to clarify sugar.

Animal caseine, the portion of milk which is coagulated by rennet, and some acids out of the body, and by the gastric juice in the stomach, constitutes curd. In the milk it is kept in a fluid state by the alkaline principles present. These are neutralised by the acids.

Gelatin abounds in most animal substances, and is common in proportion to the youth of the individual. It exists in bones, ligaments, tendons, membranes, skin, muscles, as well as in a portion of the horns of animals. The skin of fish, much of their substance, and the swimming-bladder of the sturgeon, are formed of gelatin. It is remarkably bland and nearly insipid, as may be remarked in any solution of isinglass. Gelatin is not of common occurrence in the vegetable kingdom, and it is distinct from vegetable jelly. It occurs, however, in the *Protococcus nivalis*.

Gelatin is the opposite of albumen in its qualities; in cold water it swells, is not transparent, is soft, and somewhat elastic. The gelatin of isinglass and of young animals is slowly but completely soluble in scarcely tepid water, while that of old animals, of skins, and of hoofs or feet, requires warm water for its solution. The solution, when of a certain strength, gelatinises into a tremulous or solid jelly. It is a highly nutritious principle, but its digestibility is, in popular estimation, much overrated.

Mucus is a principle probably found only in animal structures, unless it exists in some plants of the tribe of *Boraginaceæ*. It differs from albumen principally in not being coagulable by heat, while it differs from gelatin in not being precipitated by vegetable astringents, though tannin coagulates the watery combinations of mucus: neither does a concentrated solution of it gelatinise on cooling. Mucus is a constituent of most of the secretions of animals, particularly of the membranes termed mucous. It is deemed both nutritious and of easy digestion.

Osmazome, animal extractive, or alcoholic extract of flesh, is deemed the principle to which meat owes its sapid taste and odour when dressed. Berzelius is disposed to refer these qualities to a watery extract of flesh, which he terms *zomoidin*. Osmazome is by no means a simple, but, on the contrary, a very compound substance, consisting of at least two different extractive materials, lactic acid, several salts, alkalies in combination with hydrochloric acid and lactic acid, &c.

It is probably limited to the animal kingdom, though a substance strongly analogous to it is found in many mushrooms, or fungi, namely, the common mushroom (*Agaricus campestris*), the *A. muscarius*, *A. bulbosus*, *A. thejogalus*, and in the sporidia of the *Elaphomyces officinalis*. This principle is not soluble in alcohol, and to distinguish it from osmazome it is termed Pilzosmazom; to it different fungi owe, when dressed, their savoury odour, resembling that of animal food, and probably a portion of their nutritious property.

Osmazome exists sparingly in young and white meats, which consequently are deficient in savour; it is more abundant in that of animals of which the flesh is red, such as beef and mutton; it exists chiefly in the fibrous organs, or combined with fibrin in the muscles, but the tendons and gelatinous organs are, in a great measure, destitute of it. Animals with dark-coloured flesh, such as the hare, and different kinds of game, possess most, and hence are much esteemed by the lovers of savoury viands.

Gluten is, of all vegetable principles which occur in considerable quantity, the one which contains most azote, having from 14 to 20 per cent. Cafeine, or the alkaloid of coffee, possesses a much larger proportion. Gluten is met with, associated with starch and other matters, in the seeds of the cereal grains, in several other seeds, in many fruits, and in all green and other sappy parts of plants which yield feculæ. When separated from the principles with which it is usually associated, it is, when moist, a white, soft, elastic, and highly glutinous substance (bird-lime); when dry, it is white or whitish gray, hard, of a dull shining and conchoidal fracture. It is without smell or taste, insoluble in and heavier than water. Under ordinary circumstances, about a fourth part of what is termed gluten consists of a principle called *gliadin*. What remains after the removal of this and other matters present with it, is, according to Taddei, pure gluten, which he names zymoian. In the fleshy seeds of pulse, such as beans and peas, exists a substance resembling gluten, called *legumin* and also *vegeto-animal substance*.

Gluten is found in many esculent plants, such as the leaves of cabbages and cresses, and in other edible cruciferous vegetables. Of the nutritious powers of gluten, separate from the starch, fat, gliadin, &c., with which it is always associated, nothing certain is known. In a state of combination, such as that of wheat-flour, it is highly nutritious. Such also is the character of the seeds of peas, beans, and other edible pulse.

Fluids which contain at the same time any of the varieties of sugar and of gluten, or gluten-like principles, are capable, under favourable circumstances, of undergoing the vinous fermentation. A kind of fermentation occurs, by the agency of the gluten, in the conversion of wheat-flour into bread.

Emulsin (vegetable albumen, vegetable casein, or amygdalin) occurs in most of the elaborated juices of plants, and in many dry parts of plants, namely, in all oily seeds which when triturated with water form an emulsion. The real nature of this principle is not clearly ascertained. Many chemists deem it identical with animal albumen; others consider it identical with the casein of the milk of animals; while others pronounce it to be gluten. To Gmelin it appears distinct; he has accordingly given it the above name. Legumin is the term given to some forms of this principle.

II. Proximate principles which consist of oxygen, hydrogen, and carbon, called hydro-carbonates.

Gum is a principle of vegetables, in all of which, but mostly in the soft parts of them, it is found; in some, however, it abounds so much as to form their chief characteristic: they are thence called mucilaginous, or gummy, such as the carrot, parsnip, &c. Gum is colourless, but from admixture of other matters it is often of a yellow or brownish hue, transparent or translucid, of an insipid rather sweetish taste, and not crystallisable. When pure, it is entirely soluble in water, whether warm or cold, forming with it a tenacious fluid; it is insoluble in alcohol. In the state of solution in which it occurs in plants, of which it forms the chief material for their nutriment, it is termed *mucilage*. From some trees, either by spontaneous cracks or incisions, it exudes and concretes on the bark, as is seen in the various acacias, which yield the *gum arabic*, the plum, and cherry trees, &c. There is some difference in chemical character in the various sorts of gum, according to the plant which yields it, but these scarcely affect its nutritive properties. The principle which is found in many fruits, such as the gooseberry, currant, orange, &c., which is *vegetable jelly*, is regarded as a kind of gum, though designated *pectin*. This is neither acid nor possessed of basic properties, and the reason why it so often seems sour is by being united with vegetable acids (malic, citric, &c.), which communicate to the juices of these fruits their taste, and also enable them to redden litmus paper. The grateful and cooling properties of such fruits is therefore chiefly due to the vegetable acids, while their nutritious qualities depend upon the pectin and other principles. Some of these, such as plums, apples, gooseberries, contain 73 to 80 per cent. of water. (See Johnston's 'Chemistry of Common Life.')

Mucilaginous vegetables are rarely fit for use when growing wild; but they are much ameliorated by the processes of horticulture, having their bulk increased and their qualities improved; those which are bitter or narcotic, as endive, lettuce, sea-kale, &c., being by blanching rendered mild and safe, or by being served to table while young, as asparagus. The difference in flavour of such vegetables is due to the principles with which the gum is associated; but their nutritive properties are owing to the gum, which even when taken alone, though mawkish, and at last repudiated by the palate, is certainly adequate to the support of the human frame for many weeks or perhaps months. During the harvest of gum at Senegal the Africans live entirely upon it, eight ounces being the daily allowance for each man. In general they become plump on this fare, and indeed such should be the result, if the calculation be correct which assigns as great nutritive power to four ounces of gum as to one pound of bread.

Sugar is a principle much more abundant in vegetable than animal fluids; it exists however in small quantity as a constituent of the bile, and in the milk of many animals; and it is formed in large quantity as a product of perverted action of the digestive and assimilating organs, in the disease termed diabetes. [DIABETES.] In chemical composition sugar does not differ greatly from gum, except in having a greater proportion of carbon. This additional proportion however is sufficient to confer upon it considerable differences in character. Sugar is of different kinds, according to the plant which yields it, and according to the part of the plant from which it is obtained. Sugars are therefore divided into those which are crystallisable and those which are not, and likewise into those which are susceptible of fermentation and those which are not so. The sugar of the sugar-cane is the most perfect example of those kinds which are both crystallisable and capable of undergoing fermentation; sugar of milk and mannite are examples of the second class. A remarkable feature presents itself in sugars of the first class; for, while susceptible, when dissolved in sufficient water, of the vinous or acetous fermentation, they greatly assist, when concentrated, in preserving vegetable substances, either when naturally present in them, as in many fruits, grapes, raisins, prunes, &c., or when added artificially in making conserves, jellies, &c. Those fruits which grow in seasons favourable to the elaboration of much saccharine matter in their tissues not only keep better, but are more wholesome than when grown in less favourable years. [SUGAR.]

Honey contains a variety of sugar, which is both nourishing and capable by fermentation of yielding mead, which was long the favourite beverage of the ancient Briton. Many fungi, or mushrooms, contain a peculiar kind of sugar, which contributes to render them nutritious.

Starch possesses a larger proportion of carbon than sugar and gum: by removal of this additional proportion of carbon it is reduced to the state of one or other of those principles. This process of reduction occurs spontaneously in the course of flowering in plants, and in the stomach during digestion. When combined with gluten, it is susceptible of fermentation, and by undergoing the *panary* fermentation forms bread, one of the most important articles of food in civilised life. As this is ordinarily managed, some portion of the flour is made to yield up a certain amount of its carbon; but the precise nature of the change which the flour undergoes during this action is not clearly understood. The digestibility of the flour is however greatly increased by this process; and by various admixtures, chiefly of common salt, the taste is improved. [BREAD.]

Starch exists largely in plants, but more abundantly in some parts than others: such as many seeds, particularly of the cereal grains, rice, barley, maize, and millet, in which it occurs in great purity; in wheat along with gluten; with saccharine matter in oats, and some leguminous seeds; with a viscid mucilage in potatoes, rye, and Windsor beans, and occasionally with an acrid principle, which can generally be dissipated by heat, as for example the *Jatropha Manihot*, which yields tapioca. Though seeds and roots yielding starch in abundance are all comprehended under the term *farinaceous*, there are essential differences between them according to the principles with which it is associated, which cause them to differ in their digestibility, and consequently in their eligibility and suitableness for different ages and individuals. Flour, starch, arrow-root, cassada-flour, or tapioca, salep, sago, and other similar preparations, are all merely varieties of the same principle. Starch is not only highly nutritive, but one of the blandest and most wholesome articles of diet, capable, in due proportion, of being used for the food of tender infants, and not improper at any subsequent period of life, though during youth and manhood it requires other principles to be taken along with it.

Oils and *fat*, however much unlike in some respects to the other principles arranged under this head, are formed out of precisely the same constituent elements; and during digestion the stomach brings even the most apparently dissimilar into a degree of relationship more intimate than might have been anticipated. The chief difference between them and the alimentary substances already mentioned, is in their greater proportion of hydrogen. Sugar and starch are both susceptible of fermentation, during which a portion of carbon is removed from each by combining with oxygen and escaping in the form of carbonic acid gas:—from starch in the early stages of fermentation, during which a portion of carbon is taken which brings it to the state of sugar; from which again a proportion of carbon and of oxygen is taken, and alcohol produced, the hydrogen remaining undiminished in quantity:—and as alcohol is merely an oleaginous body of a weak kind, the analogy is complete; for all farinaceous and saccharine aliments undergo changes in the digestive organs before they can be assimilated in the system, similar to what occurs in fermentation, namely, being converted into oil. [DIGESTION.]

Oils are insoluble in water, and therefore, though highly nutritive, they are not available for the support of the body till their immiscibility with water has been overcome. Hence they are apt to oppress the stomach during the early stages of digestion, if taken alone without being mingled with substances which facilitate their union with water. When this is accomplished they are very readily assimilated, as, according to Dr. Prout, "albuminous and oleaginous principles may be considered already fitted for the purposes of the animal economy without undergoing any essential change in their composition."

Oils are either fluid or concrete, and both forms occur in the animal and vegetable kingdoms, though in the latter they are most generally fluid.

Acids are present in many vegetable substances which affect the digestive organs in various ways, though they may not contribute directly to the nourishment of the system.

III. Alimentary principles which do not contain carbon.

Water is the only one of these which it is necessary to notice. This is essential to the existence of all organised beings in whatever way it is introduced into their tissues. Not only is it introduced by human beings in the state of common water, and many beverages of which the chief part is water, but our ordinary articles of animal food contain, on an average, 75 per cent. of water, and only 25 per cent. of nutritive matter; and many of our vegetables contain a still larger proportion.

Such are the chief principles employed by man in a state of civilisation for his subsistence. But it is not enough that a sufficient quantity of one or more of these be swallowed. The function of digestion must be called into action to enable the crude materials to be assimilated. This is partly excited by the mere presence of a substance in the stomach, but more effectually when that substance is in itself of a stimulating quality, or is accompanied by certain accessories either added during the preparation of the food or at meal-times. Such accessories are termed condiments, which either make the food more grateful, or exercise a beneficial influence over the stomach during the process of digestion. The desire to eat is rarely so great when insipid food is offered to an individual as when savoury viands are presented. The very odour or aroma of these excites the salivary glands to more abundant secretion of saliva, which is a preparation for the digestion of the food about to be taken. Though the mere application of heat in the process of cooking developes an aroma from many substances which were previously devoid of it, either by altering the chemical composition of the material, or by volatilising a principle latent in the substance, yet many adventitious articles are used to assist in increasing or modifying this odour, or to correct certain qualities in particular kinds of food which are either disagreeable or injurious. Respecting the most common of these a few words may be allowed. That condiment which is of most universal requirement and utility is salt, or chloride of sodium. It is the only one which is indispensable, for not only does it exist in the milk which forms the earliest nutriment of the infant, but at all subsequent periods of life it is needed. Independently of the part which this compound performs in the stomach during digestion, it is still further serviceable in the blood, and more so in the blood of man than of any other being, as Berzelius has remarked that the blood of man contains three times more hydrochlorates than that of the ox. Besides, the use of salt greatly benefits the alimentary canal and hinders the generation of worms. [ANTHELMINTICS.] It is one of the most ready means of rendering insipid food acceptable to the palate, as is noticed in one of the earliest compositions that have come down to us. "Can that which is unsavoury be eaten without salt?" (Job vi. 6.) Perhaps the next most important condiment is vinegar, which, like most vegetable acids, when taken in moderation, greatly assists in promoting the digestion of young meats of a gelatinous kind, such as veal.

Mustard and pepper of different kinds are also useful, and more so in warm than cold countries, as they rouse the languid stomach, and enable it to effect the digestion of the food. Hot pickles, from containing vinegar at the same time, are often advantageous when used in moderation, but the abuse of such articles produces many serious effects, particularly obstruction of the liver, with its long train of disorders. The use of spices and aromatic agents not only renders the food more pleasant but enables the stomach to bear a larger quantity. Hence they are too often made the means of leading the gourmand to be guilty of excess; and that cook is often most prized who can most cunningly minister to the pampered appetite. This is perverting cookery, a highly proper and commendable art, from its legitimate end. "In the hands of an expert cook, alimentary substances are made almost entirely to change their nature, their form, consistence, odour, savour, chemical composition, &c.; every thing is so modified that it is often impossible for the most exquisite sense of taste to recognise the substance which makes up the bases of certain dishes. The greatest utility of the kitchen consists in making the food agreeable to the senses, and rendering it easy of digestion. But its perfection seldom stops here: frequently among people advanced in civilisation the object to which it aspires is to excite the appetite, to appease capricious palates, or to satisfy luxurious vanity. Then, far from cookery being a useful art, it becomes a real pestilence, carrying with it a train of diseases, and not unfrequently the premature death of many of its infatuated votaries." (Majendie's 'Physiology.') [MILK; WATER; WINE.]

A few remarks are appended to serve as a guide in the use of food and to avoid errors. "Though man is omnivorous, and can subsist on either animal or vegetable food—an arrangement which fits him to dwell in any part of the habitable globe,—yet he is subject with regard to the actual material of his diet, in a remarkable manner, to the influence of climate, since a particular kind of aliment, which is very appropriate in one country is improper in another; thus, as we advance from the equator towards the poles, the necessity for animal food, or its equivalent in a highly nitrogenous class of vegetables, becomes greater, till, in the very north, it is the sole article of subsistence, except a few cruciferous plants, especially *cochlearia* or scurvy-grass, abounding in nitrogen. Animal food, from containing nitrogen, is more stimulating, and, therefore, less suitable for hot climates, where, on the contrary, saccharine, mucilaginous, and starchy materials are preferred; hence, in the zone of the tropics, we find produced in abundance, rice, maize, millet, sago, salep, arrow-root, potatoes, bread-fruit, banana, and other watery and mucilaginous fruits. Quitting this zone, we enter that which produces wheat, and here, where the temperature is lower, we find united with the starch of this grain that peculiar vegetable principle (gluten) possessing all the properties of animal matter, and yielding nitrogen and ammonia by its decomposition. Thus, by a gradual and insensible transition, nature furnishes to man the food which is most appropriate for him in each region. In the subtropical zone vegetable diet is still preferred, but, in chemical composition, the favourite articles approximate animal substances. This holds also in the temperate zone, not only in respect of wheat, but also in the chesnut, which is almost the sole means of subsistence in some of the mountainous regions of France, Italy, and Spain, though instead of the gluten of wheat, this seed contains albumen, the relation of which to animal food is even closer than that of gluten. In reviewing the geographical distribution of the cereal grains, we find that starch nearly pure is produced in the greatest abundance in the hottest parts of the world, particularly in rice and maize; it becomes associated in the subtropical regions with an equivalent for animal food; and in still colder regions, where wheat fails, oats and barley take its place. These, though possessed of less gluten than wheat, are, nevertheless more heating, and therefore, better calculated for northern latitudes. The inhabitants of Scotland and Lapland, with their oaten and barley or rye bread, are thus as thoroughly provided with the best food, as the Hindoo with his rice, or the South American with his Indian corn or maize." (Dr. Robert Dickson: partly founded on an article by Parent Duchâtelet, 'Aliment,' in Dictionnaire de l' Industrie.)

An infringement of the laws deducible from these facts leads to serious (often fatal) consequences. Englishmen going to India or other hot countries, and continuing the habits of their colder native clime, instead of adopting the simpler and more rational diet of the inhabitants, soon induce diseases of a formidable kind. Eating animal food, frequently in excessive quantity, and drinking strong brandied wines, soon cause affections of the liver. (See 'A Treatise on the Diseases of the Liver,' by George Hamilton Bell, M.D., late Resident Surgeon, Tanjore; Edin., 1833, p. 17.) On the other hand, feeding young children in the cold winters of England on rice to any extent, is extremely injurious, leading especially to strumous diseases, particularly of the eye.

Where strengthening the body is the object, and bringing it up to the highest point of health and vigour, a diminution of the fluids in use, and avoiding as far as possible articles of a watery consistence, is requisite. A very large proportion of all substances used as food consists of water. Even lean beef has as much water in its composition as the potato and plantain,—that is, 78 per cent. While using such articles at the principal meal, or dinner, it can scarcely ever be necessary to use fluids or diluents at the same time; yet most persons begin that meal with soups, some very *maigre*, and drench the stomach with water, beer, and other liquids, scarcely any of which are proper, save in a very restricted quantity. When liquids are useful, they may be taken about four hours after the solid meal, whether tea or alkaline drinks, such as soda water or Seltzer water. (See Prout 'On Diseases of the Stomach.') [ALKALIES.] All the most skilful trainers of those preparing for athletic feats rigidly enforce attention to this rule, invariably putting those under their care on what is termed a *dry diet*. Attention to this simple condition will often greatly improve the health of valetudinarians. (See 'Pedestrianism,' by Walter Thom, with an 'Essay on Training,' by the celebrated Captain Barclay, Aberdeen, 1813.) Not only is solid food digested more rapidly than liquid, but the good effects are much more permanent. The practice long indulged in of giving convalescents from acute diseases only weak broths is now mostly abandoned. The articles selected as the basis of these broths were also objectionable, being either veal, chicken, or other insipid material, and the soup often made palatable by adding spices, none of which are proper, save common salt. Young meats abounding in gelatin are less digestible, less nourishing, and in every way less proper than older meats. For persons recovering from what are termed *bilious* attacks, and paroxysms of gout, they are decidedly hurtful. Besides, by long boiling gelatin undergoes a peculiar change [GELATIN, in NAT. HIST. DIV.], which further unfits it for use, perhaps even engendering dangerous products. A well but not overdressed mutton-chop, from which *all the fat has been removed before cooking*, is infinitely better.

White fish, such as whitings, soles, and flounders are often fit for convalescents, being neither too stimulating nor too nutritious, when used without butter or rich sauces. Salt alone is proper. In some hospitals, such as St. George's, London, a fish diet constitutes a part of the diet-table. When jockeys at Newmarket wish rapidly to reduce their weight, they are never allowed meat, when fish can be obtained. (Paris, 'On Diet,' p. 223, 4th edition, 1829.) The oily and red-fibred fish, such as herrings, eels, and salmon, are not so digestible, though more nutritious. When patients in hospitals are permitted to choose their own dinner, they almost invariably select stewed eels, an indigestible food. The apparently highly nutritive power, not to say curative, of cod-liver oil, has led to its very extensive use in the treatment of strumous diseases, especially consumption. Fish, if allowed to ferment or putrify, becomes very stimulating, owing to the disengagement of ammonia. This renders it at first offensive to the sense of smell in those unaccustomed to it. The Zetlanders term such fish "blawn-fish." They are fit articles of food in cold regions, and are used by the Esquimaux. Sir Edward Parry testified to their excellence in this state.

Mushrooms, of which 27 species, native of Great Britain, are esculent, when properly prepared might be more extensively used as food, both by poor and rich, were their distinctive qualities better studied and known. (See Dr. Badham on the 'Esculent Fungi of Great Britain;' and Mrs. Hussey's 'British Mycology.')

FOOD, PRESERVATION OF. [ANTISEPTICS.]

FOOLS, FEAST OF. This was a festival anciently celebrated in different churches and monasteries of Europe and the East, but most perhaps in those of France upon New Year's Day, when every kind of absurdity, and even indecency, was committed. It appears to have been in fact a continuation of the heathen celebration of the January Kalends. Mock popes, cardinals, and bishops, were elected, with ludicrous dancing and singing, intended it is said to ridicule exploded druidism. The council of Basel in 1435 expressed its detestation of this and several other festivals which were then celebrated, and its abolition, at least in one district, was ordered by an arrêt of the parliament of Dijon in 1552. The reader who would know more of this festival may consult Du Cange's 'Glossary, *v.* KALENDÆ,' and Du Tilliot's 'Mémoires pour servir à l'Histoire de la Fête des Foux, qui se faisoit autrefois dans plusieurs Eglises,' 4to., Lausanne et à Genève, 1741.

FOOT. [WEIGHTS AND MEASURES.]

FOOT-BALL, a ball made of a blown bladder cased with leather to be kicked by the foot; used by metonymy for the diversion of driving the ball itself. This was an early and favourite sport with the English. Fitzstephen mentions it among the games of the Londoners in the time of Henry II. Pepys, in his 'Memoirs,' vol. i. p. 324, A.D. 1664-5, says, "January 2, to my Lord Brouncker's by appointment in the Piazza, Covent Garden: the street full of foot balls, it being a great frost." James I. forbade it to be practised near his court as dangerous; but Addison in the 'Spectator,' speaks of a "football match," as one of the village sports patronised by Sir Roger de Coverley. It is still a game much practised by school-boys, and in many rural districts. At Derby it was played till a very recent period by opposing parishes, and not unfrequently attended with serious accidents.

FORCE, a mechanical term, which though it be sufficiently understood in its common and popular meaning, requires some consideration before its strict and philosophical sense can be comprehended.

The term *force* always implies the existence of some cause which produces a visible mechanical effect. Thus the cause of motion and the cause of pressure are both forces: again, difference of effects must be attributed to difference in the producing causes: thus, greater or less velocity, and greater or less pressure, are both attributed to differences in the causes of velocity or pressure. But on the other hand, effects which are the same in one point of view may differ in another; thus, bodies of different weights, let fall from the same heights above the ground, will strike the ground with the same velocities, but with different degrees of effect upon the substance which they strike. Again, if a ball be thrown upwards with a velocity *a*, which carries it to a height *b*, it will, when thrown upwards with twice the velocity, ascend through four times the height *b*. Here, then, considered with respect to one effect, the second force should seem to be twice the first: considered with respect to another, the second seems four times the first. Such difference of appearance in the numerical quantities of different effects led at one time to long and warm disputes on the *proper* method of measuring force, all of which a clearer knowledge of mechanics has shown to be of very little use. One distinct meaning, with care not to assume the consequences of any other meaning as necessarily deducible from the first, will enable the mechanical reasoner to establish the whole doctrine of *statics*, or *equilibrium*: another, the whole doctrine of *dynamics*, or *motion*.

It should seem that these two (so called) *forces* should have different names; but custom has settled otherwise. We proceed to the definitions of force.

In the theory of equilibrium, *force* is a synonym of *pressure*, and *weight* is its measure. The notion of force is here derived, most probably, from the sensation which accompanies muscular effort. Wherever pressure is produced we can find a weight which will supply the place of the pressure: thus, if a string of indian-rubber, hanging from a fixed point, be extended by the hand placed at its lower extremity until its length be doubled, we can, by suspending a weight at the lower end, find what the weight must be in order to produce the same effect. And we then say that the force which the hand exerts is the same as that of the weight. The immediate causes of the effect are very different: our own power of volition, and the connection between the earth and the weight which it draws towards it are (we may safely say, with all our ignorance of causes) extremely different things; but where they produce the same effect, we cease to think of the difference, and say that they both create the same *force* or *pressure*.

In the preceding definition of force, time is not one of the elements. But we very soon observe that wherever pressure is produced motion is prevented. Let the elastic string be suddenly cut in two, and the hand or the weight immediately descends. It is also proved that matter is incapable of producing either rest or motion in itself: if a certain rate of motion be communicated to it, it will preserve that motion unaltered till some external cause interferes. On this axiom the notion of force, as causing motion, depends for precision: the *alteration of velocity* is the evidence of the existence of force.

When force, in the sense of pressure, is considered as the cause of motion, or rather of change of motion, we must take into account both the necessity of introducing the element *time*, and also the quantity of matter which is moved. No change of velocity can be instantaneously produced: if a billiard ball, moving 10 feet per second, be struck so as to accelerate its motion to 20 feet per second, the accession of velocity is made gradually though rapidly. A stone which has fallen for one second in a vacuum is, at the end of the second, moving at the rate of 32 feet per second: let x be any number or fraction less than 32, and there must be a moment, during the course of the second, at which the stone's velocity is x feet per second. Again, when pressure produces motion, the velocity generated in a given time is less, the greater the quantity of matter to be moved. Let different weights, the first double that of the second, be placed on a table (friction not being supposed to exist) and let given equal weights (say each one ounce) be attached to them by strings and hang over the side of the table: then, supposing the two first weights to be 16 and 8 ounces, the pressures are in both cases the same, namely the weight of one ounce; but the masses of matter moved are 17 and 9 ounces (for in both cases the moving ounce is part of the whole quantity moved). The velocities at the end of any given time are found to be *inversely* as 17 and 9: so that by the time a velocity of 9 feet per second is created in the mass of 17 ounces, 17 feet per second is created in that of 9 ounces. The connection of pressure, velocity created by pressure, and time which pressure takes to create velocity, as deduced from experiment, is contained in the following results:—

1. The same pressure continually acting upon a given mass for different times produces velocities which are proportional to the times, and augments velocity by equal portions in equal times.

2. The same pressure applied to different masses of matter (that is, to different weights of matter) during the same time, produces velocities which are inversely proportional to those masses.

3. The velocity of falling bodies is accelerated by 32·19 feet in every second: and in that proportion for all other times.

If then a pressure which is the same as that of a weight V produces motion in a mass of matter whose weight is W, during t seconds, then because the weight of V acting upon the mass of V for that time would produce $32{\cdot}19 \times t$ feet of velocity, we have

Velocity produced by V acting on V (or $32{\cdot}19 \times t$),
is to velocity produced by V acting on W (which is to be found),
inversely as V to W, or as W to V: whence

velocity acquired is $\frac{V}{W} \times 32{\cdot}19\,t$ feet per second.

If it were required to reduce the weight W, having a velocity v, to a state of rest in a given time, say t seconds, and if P were the pressure requisite to be applied to W during the t seconds to produce this effect, we must remember that the velocity destroyed by a pressure in any direction is the same as would have been created in the same time in the opposite direction, if the mass in question had been already at rest. Thus,

$$\frac{P}{W} \times 32{\cdot}19 \times t \text{ must be} = v \text{ or } P = \frac{W v}{32{\cdot}19\,t}$$

Hence, in different masses, the pressures necessary to destroy the motions in the same given time are as the products of the masses and velocities. Thus,

The pressure which will in one-hundredth of a second reduce to rest a mass of 10 ounces moving 100 feet per second, is to the pressure which will (also in one-hundredth of a second) reduce to rest 20 ounces moving 85 feet per second, as 10 × 100 to 20 × 85, or as 1000 to 1700. It is customary to call this product of mass and velocity the *momentum* or *moving force* of the body. [MOMENTUM.]

When bodies are in motion, and with a continually varying velocity, it becomes desirable to consider their motion, not at all with reference to the masses which are moved, and solely with reference to the alterations of velocity which are produced. Thus if a feather and a cannon-ball move together in the same way, the force that is exerted upon the feather is the same in motive effect (upon the feather) as that which acts on the ball (upon the ball). It is customary to ascertain the amount of velocity which would be produced in one second if the acceleration, such as it is at the point in question, continued uniformly. [ACCELERATION.] And this result is called the *accelerating force:* for which the simple term *acceleration* might be advantageously substituted. It is found by the rules of the differential calculus in the following manner (for the demonstration, see VELOCITY). If a point move in a line in such a manner that x feet is its distance from a given point in the line at the end of the time t seconds, and if x be a function of t, then the velocity of the body (v) at the end of the time t is $\frac{dx}{dt}$ feet per second, and the acceleration which that velocity is then undergoing is such as, if allowed to continue uniformly for one second, would increase the velocity by $\frac{dv}{dt}$ or $\frac{d^2x}{dt^2}$ feet. Thus, if $x = t^2 + t^3$, or if a point move through $t^2 + t^3$ feet in t seconds, the velocity at the end of that time is $2t + 3t^2$ feet per second, and its acceleration is $2 + 6t$; or (for instance) at the end of 10 seconds the velocity (320 feet per second) is undergoing acceleration at a rate which would, if continued undisturbed for one second, add 62 feet in that second: or at the end of the *eleventh* second, the velocity would be 382 feet per second.

If f be this accelerating force, we have then

$$v = \frac{dx}{dt}; \quad f = \frac{dv}{dt} = \frac{d^2x}{dt^2}; \quad v\,dv = f\,dx.$$

These are called the *equations of motion.*

Any unit of time might be chosen instead of one second, but not without the following caution. Let g be the velocity generated by a force acting uniformly for one second; then $60\,g$ is the velocity produced in 60 seconds or in one minute. If then we measure the acceleration by g, when the unit is one second, it might seem that we should use $60\,g$ instead of g, when the unit is one minute. But it must be remembered that when we use the minute as a unit of time, we must measure velocities by the spaces which would be described in one minute. Now, in the preceding, $60\,g$ means that the body, at the end of one minute, is moving at the rate of *60 g per second;* that is at the rate of $60 \times 60 \times g$ per minute. Hence $3600\,g$ is the measure of the acceleration, when both velocity and acceleration are referred to the minute instead of the second.

Referring to what precedes, we see that accelerating forces (or accelerations) are proportional inversely to the masses in which they are produced, and directly to the pressures which produced them. Thus the pressure V acting on the weight W, produces $\frac{V}{W} \times 32{\cdot}19$ feet of velocity in every second.

The greatest difficulty in the way of the beginner is his liability to confound an increase of velocity with an increase of length described. He should carefully attend to the article ACCELERATION, by which he will see that a *velocity uniformly increasing* causes unequal spaces to be described in equal successive portions of time; while a *uniformly increasing length described* means a uniform velocity, or a velocity which does not change at all.

FORCES, IMPRESSED AND EFFECTIVE. When various pressures act at different points of a system, the forces which act upon any one point are not those which would, by themselves, produce the motion which that point really has, in consequence of the motion of the system. Thus, suppose a pendulum with two balls, one above and the other (which we suppose to be much the heavier) below the point of suspension. The forces which act on the upper ball would, if it were free of the larger one, cause it to descend; while, in consequence of the connection of the two balls, the smaller actually does vibrate like a pendulum turned upside down, or as if its gravitating tendency were upwards instead of downwards. Here is an instance in which the impressed force acts downwards and the *effective* force upwards; that is, the motion which actually ensues is such as would require a force acting upwards to cause it.

One of the most important principles in dynamics is that known by the name of D'Alembert, and is enunciated thus: the impressed forces are altogether equivalent to the effective forces, or if the directions of the latter were all changed, the former would equilibrate them. Suppose an infinitely small portion of time to elapse, during which the different small masses into which the system may be divided receive certain infinitely small accelerations or retardations. From these the effective forces may be deduced, for they are the forces which would severally produce the actual changes of velocity which take place. If then, forces equal and contrary to the effective forces thus deduced were applied at each point, all the motion created by the impressed forces would be destroyed; that is, the effective forces are such as would (applied in contrary directions) prevent the impressed forces from producing any motion. This proof might be put into more accurate language, but it is in substance the one which is usually given. [VIRTUAL VELOCITIES.]

FORCES, PARALLELOGRAM OF. Any two forces acting at the same point, and represented in magnitude and direction by two straight lines, are equivalent to a third force which is represented in magnitude and direction by the diagonal of the parallelogram constructed with the two lines as its sides. [COMPOSITION.] This theorem is frequently called that of the *parallelogram of forces.*

FORCES, PHYSICAL CORRELATION OF. [PHYSICAL FORCES.]

FORCING, in horticulture, is the art of hastening the growth and maturity of flowers, fruits, and vegetables by artificial means.

Many of our finest exotic fruits are indigenous to warmer countries, and would scarcely ripen even in our warmest seasons; but by this art they are brought to great perfection in cold climates, and by advancing or retarding artificially the growing season of hardy kinds they also can be had in regular succession throughout the greater part of the year.

Although forcing to any extent is but of recent date in England, yet it appears to have been practised in other countries at a very early period of time. Sir Joseph Banks, in the 'Hort. Trans.,' cites some epigrams from Martial, to show that hothouses were not unknown to the Romans, and arrives at the conclusion that in all probability they had both vineries and peach-houses, formed of *talc* instead of glass, which is now commonly used. Pliny tells us that Tiberius, who was fond of cucumbers, had them in his garden throughout the year by means of (*specularia*) stoves, where they were grown in boxes, wheeled out in fine weather, and replaced in the night or in cold weather (Plin. 'Hist. Nat.,' xix. 23); whence it may be inferred that forcing houses were not unknown to the Romans, though they do not appear to have been in general use. This branch of horticulture was almost unknown in Britain until the end of the 17th or beginning of the 18th century, and Lady Mary Wortley Montagu, on her journey to Constantinople in the year 1716, remarks the circumstance of pineapples being served up in the dessert at the electoral table at Hanover, as a thing she had never before seen or heard of. Sir Joseph Banks justly remarks, had pines been then grown in England, her ladyship, who moved in the highest circles, could not have been ignorant of the fact. They were however certainly grown at Hampton Court in the reign of Charles II. It is said that the discovery of peach-forcing in Holland arose from an old Dutch gardener having, in a bad season when his peaches would not ripen, accidentally placed the sashes of a hotbed over them, which had the effect of ripening them. Even after forcing was practised to a considerable extent, its principles were so little understood, that fruit procured in this way was nearly destitute of that natural flavour which it acquires when exposed to the genial influence of the sun's rays and to free ventilation.

The fruits of warmer climates, growing in a wild state, enjoy a greater degree of light than it is possible to give them in this country at any season of the year, and this is one of the most important circumstances to attend to in the art of forcing. Nature is in all respects the best guide in these matters, and care should be taken to imitate her as far as possible; first, by taking care that forced plants are exposed to all the light that can be collected; and, secondly, by preserving a due proportion between the quantity of heat and light to which forced plants are exposed; in other words, by not forcing too hard at a season when the sun's rays are least powerful, thus acting in direct opposition to the laws of nature. Attention to this is the corner-stone of the whole process. When early crops are more desirable than high-flavoured fruit, gardeners are obliged to apply heat without reference to the intensity of light; but if this is not the object, forcing should never be commenced before the spring, in order that the fruit may have the greatest degree of light when ripening. These principles are now generally understood and appreciated, and consequently our peaches, grapes, and other forced fruits are even superior to those grown under the clear skies of the south of Europe.

Mr. Knight, president of the London Horticultural Society, recommended the temperature to be kept much lower during night than is generally done, and remarked, "A gardener in forcing generally treats his plants as he would wish to be treated himself, and consequently, although the aggregate temperature of his house be nearly what it ought to be, its temperature during the night relatively to that of the day, is almost always too high." In one of his vineries he always wished the temperature in the middle of a bright day in summer to rise to 90°, and when the leaves of his plants were quite dry, he did not object to 10 or 15° higher. But he most justly adds, that if this is accompanied by a high temperature at night, "it exhausts the excitability of the tree much more rapidly than it promotes its growth or accelerates the maturity of the fruit, which is in consequence ill supplied with nutriment at the period of its ripening, when most nutriment is probably wanted."

The same experienced author recommended the plants for forcing to be rendered, by previous treatment, as excitable as possible, which may be done by ripening the wood early in autumn, and putting the tree into a state of repose, ready to be roused into action by the application of heat.

It appears to be a general rule that plants from warm countries endure with impunity a very high degree of temperature, while those of more temperate regions are impatient of artificial heat, and hence the difficulty of forcing the plants of northern climates; for example, the same degree of heat in which vines flourish would be much too high for cherries, which throw off their blossoms after expansion without setting their fruit. The reason of this seems to be the following: each plant is adapted to the peculiar circumstances in which it is naturally placed; the natives of warm climates are formed to endure heat, and those of higher latitudes to suffer cold; and when these circumstances are reversed, those of cold countries being placed in excessive heat, and those of warm regions in unusual cold, the former are excited by far too much and too rapidly, so that flowers and fruit are developed before the leaves have had time to organise matter to support them; and the latter, if they endure the cold, are not excited, and remain in a languishing unhealthy state. These reasons will at once show the extreme caution which is necessary in forcing the fruits of northern climates, and will at the same time suggest the treatment that plants of such a description require, and which both reason and experience agree in recommending to those who would be at all successful in the art. Firstly, the increase of temperature must be slow and gradual, and never at its highest point exceed 60° or 65° of Fahr. with artificial heat; air must be freely introduced, particularly in fine bright weather, and the house so constructed as to admit of the greatest possible quantity of light, as for instance by having moveable sashes which can be taken off and put on at pleasure.

The Dutch have long been celebrated as excellent forcing gardeners, and as their manner of performing the operation is peculiar, a description of it may be interesting. The principal feature in their system is conducting the operation chiefly in frames, and pits heated with fermenting dung. The trees employed in forcing are generally taken from a wall in the open air, planted in a rich border of leaf mould, and trained to a trellis a few inches below the glass; here they remain until they have ripened their fruit, after which they are moved back to the wall until wanted for the same purpose in some succeeding year; they never force from the same plant two years in succession. Their system of employing dung instead of fire heat gives them an excellent opportunity of forcing vegetables, such as French beans, endive, lettuce, &c., which are either placed on, or plunged in, the bed in the inside of the frame.

Although pit and frame forcing is a principal feature in the horticulture of Holland, yet they have now, as well as in this country, more elevated structures.

The Dutch plan of forcing has been practised to a considerable extent in gardens in Britain, particularly in that of P. C. Labouchere, Esq., Hylands, near Chelmsford, of which a full account is given in the first vol. of the 'Gardener's Magazine,' and another interesting paper upon the same subject, communicated to the Horticultural Society by M. Lindegaard, is published in their Transactions, Series I., vol. v. The best information regarding the scientific principles of forcing is contained in the numerous papers scattered through the Transactions of the London Horticultural Society, communicated by Mr. Knight and other scientific individuals, and in Lindley's 'Theory and Practice of Horticulture.' The best practical works upon the subject are those from the pens of Speechly, Sandars, M'Intosh, Errington, Glendinning and Robert Thompson, the contents of which are chiefly given in Loudon's 'Encyclopædia of Gardening,' and in the columns of the 'Gardener's Chronicle.'

FORCING-ENGINE. [FIRE-ENGINE.]

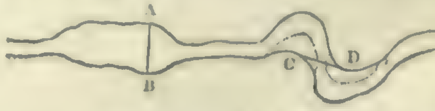
FORD, a name applied to that part of a river where the water is sufficiently shallow to admit of wading through it, and thus crossing over without having recourse to a bridge, a ferry, or other similar means of passage.

Some rivers are never fordable, others are always so; in some the fords are temporary as to season though permanent as to place, and in others they frequently change their situation. Rivers whose banks are steep and course straight are rarely fordable, for in such the water is generally too deep or too rapid to admit of fording. Small and regular streams issuing from springs in flat countries are generally fordable at all times and in all parts. The most common cases, however, are those of temporary and changeable fords. Of the first of these it is observable that when a river has once formed its bed in a soil of a certain degree of tenacity it seldom changes its channel, so that its shallows and deep parts remain constant, and, if the former permit of being forded, nothing but a rise of the waters renders the ford impracticable. This rise depends entirely on the rains which fall into the basin of which the river is the drain and the size of the basin itself, to which two circumstances the river is generally proportionate. If the basin be large and subject to frequent rain the fords will frequently be rendered impassable; if the rains are of long duration, the passage of the ford will be interrupted for a time proportionably long. The channel however remaining permanent the ford may again be passed as soon as the excess of water has flowed off. Such fords have generally been used long before bridges were constructed, and as travellers from a distance sometimes found the ford impassable on arriving, hostelries for their temporary reception were constructed on the banks. Such has been the beginning of many towns whose names still commemorate their origin, as Chelmsford, Bedford, Oxford, Stratford, &c.

Such rivers as flow through a loose soil, as sand or gravel, have generally a very winding course and are constantly shifting their channel, that is, the deep part (which the Germans call the *thalweg*) of their bed. These rivers though they present the greatest number of fords are constantly varying the situation of them, so that they are not only temporary as to season but also as to place. The rains by increasing the mass of water increase the strength and rapidity of the current, by which the bed is ploughed up and deepened in an irregular manner. Banks also are carried away and others formed in parts that before were deep. Thus after every flood the place of the ford is changed.

In the case of torrent rivers, such as those of Italy, fords are very common, but they are subject to be rendered suddenly impassable, or shifted, the waters rising with frightful rapidity to a great height and acquiring amazing force. They however soon subside, and, unless they have deepened the channel, cause no other inconvenience than a very temporary delay.

In military operations fords are of the greatest importance. The inhabitants on the borders of a river generally know where they are, but as their indications cannot always be relied upon, particularly in an enemy's country, the fords must be looked for. They are generally found either in the widest part of the river, or in the direction of the diagonal line that joins the salient angle of one side to the salient angle of the other side, as A B or C D.



In the first case the waters spread out in the wider part of the bed of the river, and are therefore less deep; and in the second, there is always a deposit in front of the salient angles (as indicated by the dotted lines) and consequently the water is more shallow in those parts.

Fords for infantry should not exceed the depth of three feet, and for cavalry that of four feet. These are the extreme depths, and if the current be somewhat rapid it is dangerous to risk fording through more than two feet water for infantry and three for cavalry. The bottom must also be firm and even. Mud, weeds, or blocks of stone are great obstacles—loose sand is also bad as a ford for cavalry, for, being stirred up from the bottom by the horses, it is carried away by the stream, and the ford thus becomes so deep that the last horses in such case are frequently forced to swim. The opposite bank must also be easily accessible and clear, for it is useless to cross a river when, on gaining the opposite side, your further progress is impeded by rocks or impassable forests, thick brushwood, or swampy ground. Having discovered a ford, it is indispensable to mark its situation, and if some time should have elapsed previous to conducting the troops to it, the ford should be again examined in order to be sure that the waters have not risen, or that the enemy may not since have rendered it impassable, which may be effected in different ways. Other considerations are necessary when the ford is to be passed in presence of an enemy, but these belong to a different subject.

FORECLOSURE. [Mortgage.]

FOREMAN. [Jury.]

FORESHORTENING (in Italian *scorciare*, *scorcio*) is a term chiefly applied to anatomical drawing when one or more limbs of a figure, or its entire body, are shown so as to be *shortened* by being viewed directly in front or nearly so, and the spectator seeing little more than its *fore* end, or that which is towards him. Thus, supposing an extended arm and hand to be nearly opposite the eye, and perpendicular to or forming a right angle with the picture, little more than the tips of the fingers or thickness of the arm would be visible. Hence, as perspective has been defined to be the art of foreshortening objects, foreshortening may be explained as linear perspective applied to the human figure, this being the principal case which admits of striking perspective effect in such objects; because when, as for the most part happens, the limbs are beheld in their full or nearly their full extent, let the attitude be what it may, the outline is little affected by mere perspective; consequently, except in ceiling-pieces, where the figures are supposed to be above the spectator, and seen from below the plane on which they stand, foreshortening—at least any considerable degree of it—is rarely required in delineating the human figure; while, on the other hand, it occurs more or less in the figures of almost all animals, their forms being more compounded and their bodies placed horizontally. An example of *foreshortening* may therefore at any time be obtained by standing either in front or behind a horse, when the hind or fore-legs, as the case may be, will be nearly concealed by those towards the eye, and the back of the animal or its length be no longer visible. In sculpture, unless it be in reliefs, the foreshortening of the limbs depends entirely upon the station chosen by the spectator himself; whereas in painting it depends upon that chosen by the painter for him; and several fine examples of it occur in the works of Michel Angelo, Correggio, and Rubens.

FOREST, an extensive tract of ground overgrown with trees alone, of one or several species, or with trees and underwood.

Forests are not only highly interesting in themselves, but are of most extensive importance, whether as regards their influence in the general economy of the globe or on local climate; as supplying to man those necessary articles timber and fuel, besides a variety of nutritious, medicinal, and tinctorial plants; or finally, as affording shelter to wild animals, which finding in them both food and security, leave man unmolested, except when the inclemency of the weather or the scarcity of food impels them to seek the inhabited country.

In taking a view of the forests which cover such immense tracts of the earth's surface, the first thing which strikes us is their variety. In one place they are composed of palms, in another of oaks, and elsewhere of pines and birch trees, &c. We are next surprised at the apparent dissimilarity of situation in which we find collected together trees of the same kind; palms in America, in Africa, and in Asia; oaks and pines in Russia and Mexico, in plains and on mountain tops. A little consideration, however, will satisfactorily account for this. Trees like other vegetables, require, according to their several natures, and independent of suitable soils, different modifications of heat, light, and moisture,[*] circumstances which, so far from being influenced by latitude alone, are much more dependent upon height above the level of the sea, the vicinity of the sea, and other circumstances, than upon proximity to or distance from the equator. Hence, not only do we find particular kinds of trees associated in those regions which are most conducive to their perfect development, but as we find regions of similar climate in different parts of the world, so do we find them producing vegetation of similar character, and thus, though the torrid zone has forests peculiar to itself, we there find also, but at different heights above the sea, the forests of what are termed the temperate and frigid zones. It is, however, remarkable and not easily accounted for, that, although the same trees seem to require similar climates, these climates do not always give birth to the same kind of plants. The greater part of our European forest trees, even the hardiest, disappear towards the Tobol and the Irtish. They do not grow in Siberia though the climate is the same. The oak, the hazel, and the wild-apple are not found from the Tobol to Dauria, although the two first appear again suddenly on the borders of the Argoun and the Amur, and the last is again found in the Aleütian islands.

According to Humboldt, whether we ascend from the plain of Oratava to the top of the Peak of Teneriffe, or from the shores of the Pacific to the summit of the Mexican Andes, we find different zones of vegetation, in which the succession of forest-trees follows, generally, the same order that is observed in passing over the surface of the earth from the equator towards the poles. Ramond, also, in the Pyrenees, and Tournefort on Mount Ararat, found in ascending these mountains, the same succession of trees as exists in passing from their particular latitudes towards the frozen regions. From this fact it has been rather rashly concluded, that certain heights correspond in the nature of their vegetation with certain latitudes: this, however, is not strictly the case, nor is the succession we have mentioned absolutely that observed in proceeding from the equator northward. The extreme heights at which certain forest-trees vegetate in the Andes are different from those at which similar trees are found in the Pyrenees, and while the birch is nearest the snow in Lapland it is succeeded in the Alps by the pine. These variations are explained by a difference in some of the elements of local climate, and by the probable fact of particular primitive distribution. It is also remarkable that in some cases forests are composed solely of some particular tree. Thus, in Lapland there are extensive forests of birch without a single tree of any other kind, and without underwood. In Mazovia also are extensive forests of nothing but birch. In Norway, Sweden, and Finland many forests consist exclusively of pine. Asia has whole woods of nothing but cocoa-nut, &c.

It has resulted from the investigations of M. Alphonse de Candolle, in geographical and geological botany, as modified by those of the late Professor Arthur Henfrey, of King's College, London, that ligneous plants established themselves in northern and temperate countries, at an epoch when the climate must have been more humid and more cloudy than it is at present. The destruction of forests to clear land for cultivation, changes the whole face of vegetation, and even to some extent (as remarkably exemplified in India) affects the local climate. Instances of this kind might be furnished from almost every part of the globe. At the present time, regions in the South of Europe, North Africa, the Canaries, the Southern United States of North America, and elsewhere, once cleared and exposed to the influence of the sun, do not become clothed again by forests such as they possessed formerly. North Europe was clothed in early times of the historical period, forming the later part of the present geological period of the earth's history, with dense forests, long since cleared away to give place to cultivated plants, and a multitude of wild plants suited to the different conditions of the soil; in like manner as the forests of North America are disappearing by degrees under the hand of man. The change is not merely one kept up by a continual effort of cultivation; the original vegetation does not always re-establish itself even when the region is deserted. New kinds of plants spread over the cleared ground, and new animal inhabitants come to check the efforts of the old forests to renew themselves. Coniferous and amentaceous plants, which form the chief constituents of forests in these regions, are phanerogamia of low organisation; and this fact leads to a conclusion of great interest in the history of plants, and perhaps of organic beings generally. The probable antiquity of the groups just named, judging from their occurrence in masses in certain countries, confirms, according to the eminent botanists whose views we are citing, the opinion that existing species are of unequal antiquity, and that the older species are of lower type.

Our European forests, generally considered, are composed of oak, elm, ash, beech, alder, poplar, willow, plane, birch, and lime, together with interspersed wild-apple, pear, and cherry-trees, dogwood, hawthorn, and service-tree; the underwood being hazel, elder, buckthorn, viburnum, dog-rose, &c. Yew and holly are the evergreens of our woods, and of coniferous trees we have the larch, different species of the pine and fir, the cypress, and the juniper.

Forests of Great Britain and Ireland.—The British isles, like other countries of Europe, were in former times much more abundantly covered with timber than they are at present. The increase of population tends to the destruction of forests by causing a demand for the productions of arable land; and this, together with the prodigal expenditure of wood, when it is abundant, and the general and long-continued neglect of any measures tending to ensure a constant supply, have been the chief causes of the great diminution of wood. But though we have now hardly any forests of considerable extent, there are perhaps few countries over which timber is more equally distributed, that is, in those counties where the soil and aspect are favourable to its growth. Woods of small extent, coppices, clumps, and clusters of trees are very generally distributed over the face of the country, which, together with the timber scattered in the hedge-rows, constitute a mass of wood of no inconsiderable importance.

---

[*] In this article, as originally published, and agreeably to what was believed at the time, atmospheric pressure was enumerated among these circumstances; but this has since been found to be a theoretical generalisation which facts do not support. Science is indebted for the correction to Dr. Joseph D. Hooker, F.R.S., who has stated that he knows of no foundation for the hypothesis that an alpine vegetation may owe some of its peculiarities to the diminished atmospheric pressure. Many plants, he observes, natives of the level of the sea in other parts of the world, and some even of the hot plains of Bengal, ascend to 12,000 and even 15,000 feet on the Himalaya, unaffected by the diminished pressure. Any number of species from low countries may be cultivated, and some have been, for ages, at 10,000 to 11,000 feet, without change. It is the same, Dr. Hooker also states, with animals (and also with man up to the elevation of about 14,000 feet); innumerable instances may with ease be adduced of pressure alone inducing no appreciable change, whilst there is absence of proof to the contrary. The affections both of plants and animals which have been attributed to this cause, appear to be occasioned in reality by the other phenomena which accompany diminished pressure of the atmosphere.—('Himalayan Journals,' vol. ii., pp. 413-415.)

In Herefordshire, Warwickshire, Northamptonshire, and Staffordshire is abundance of fine oak and elm woods. In Buckinghamshire there is a quantity of birch and oak, and also fine beech. Sussex, once celebrated for the extent and quality of its oak forests, has yet some good timber; at present its woodlands, including coppice-wood, occupy 175,000 acres. Essex, with 50,000 acres of woodland, has some elms and oaks. Surrey, Hertfordshire, and Derbyshire abound in coppice-woods. In Worcestershire is abundance of oak and elm. In Oxfordshire there are the forests of Whichwood and Stokenchurch, chiefly of beech, with some oak, ash, birch, and aspen. Berkshire contains a part of Windsor forest; and Gloucestershire, the forest of Dean; so that these three last counties are extensively wooded, and with noble trees. Cheshire has few woods of any extent, but the hedge-row timber and coppices are in such abundance as to give the whole country, especially when seen from an elevation, the appearance of a vast forest. Of the remaining counties, some have very little wood, and a few are altogether without; but the want and value of timber have given rise to a great many flourishing plantations. Of late years the flanks of the Cumbrian mountains, the sides of the fells, and the borders of the lakes, in Cumberland, Westmoreland, and Lancashire, have been extensively planted, chiefly with Scotch fir and larch. In Wales also, there is a rage for planting. In South Wales alone six millions of trees, it is said, are annually planted; if that is the case, nine-tenths of the number must come to nothing, or the whole country would be one entire forest.

Scotland has few forests of large timber, if we except the woods of Inverness-shire and Aberdeenshire. In the former of these counties the natural pine-woods exceed the quantity of this wood growing naturally in all the rest of Britain. In Strathspey alone there are 15,000 acres of natural firs; and in other parts the woods are reckoned by miles, not by acres; there are also oak woods, and extensive tracts of birch. In Aberdeenshire, in the higher divisions of Mar, there are 100 square miles of wood and plantations. The pines of Braemar are magnificent in size, and are of the finest quality. Argyleshire, Dumbartonshire, and Stirlingshire have many thousands of acres of coppice-wood, and, with a very few exceptions, the remaining counties have many, and some very extensive plantations.

Ireland has every appearance of having been once covered with wood, but at the present day timber is exceedingly scarce in that country, there being no woods, if we except a portion along the sea-coast of Wicklow, the borders of the lake Gilly, in Sligo, some remains of an ancient forest in Galway, and some small woods round Lough Lene, in the county of Kerry. The lakes of Westmeath have also some wooded islands. There are extensive plantations in Waterford, and a few natural woods, of small extent, in Cavan and Down; but Fermanagh is the best wooded part of Ireland. The want of wood however in this country, as far as it is employed for fuel, is little felt, in consequence of its extensive bogs, which furnish an almost inexhaustible quantity of peat.

Upon the whole then, though Great Britain and Ireland do not now possess any extensive forests, still there is a considerable quantity of timber, and the extent of new plantations seems to promise that we shall never be wholly destitute of so essential an article as wood. According to M'Culloch, there is annually cut down in Great Britain and Ireland timber to the value of 2,000,000*l*.

If from our own country we pass over to the continent of Europe, we shall find forests of much greater extent, particularly in the north-east.

Norway.—In the southern part of this country the mountains are covered with wood; birch, maple, pine, and fir, forming immense forests; the fir, sometimes attaining a height of 160 feet, is in great estimation for masts and building timber: in the regions of moderate elevation are aspens. The good lands have some fine forests of oak, which extend as far as Drontheim, in 63° north latitude. The forests of *Sweden* are similar to those of Norway. In the damp places there grows in abundance the almond-leaved willow (*Salix amygdalina*).

Denmark.—Of this country it may be remarked that Jutland, once covered with thick forests, has now only a few long slips on its eastern side. Holstein has very little wood. The island of Funen has some small woods, as also Sealand, in that part of it which borders on the Sound. Falstar is well wooded, and Bornholm has a good deal of birch. In all, Denmark possesses about 130 square leagues of wood, chiefly birch; there is also ash, alder, and oak, but pine and fir are scarce.

Holland possesses timber, though not in very great quantity, generally speaking; what there is, consists of beech, fir, poplar, and ash; willow grows along the canals, and the coppices are of maple, ash, hornbeam, birch, and beech, with a slight portion of oak-bushes. In Guelderland there are plantations of many miles in extent of fir and Weymouth pines, and many hundred acres have been sown with acorns. At Rhenen there are thick woods, as also at Arnheim; and many plantations have been formed on the upper Yssel of fir, pine, oak, beech, and birch.

Germany is so well-wooded that the forests are estimated to cover about one-third of the whole surface, though some consider this estimate too large. In *Hanover* are some fine groves, and a quantity of limes and willows planted in rows. This kingdom also includes about three-fifths of the Harz forest. In *Westphalia* there are very extensive forests, one in particular, in the neighbourhood of Osnabrück, is about 32 miles long and 20 broad. These woods, in which there is abundance of the finest oak timber, are stocked with swine, and furnish the hams so generally esteemed over all Europe. In *Brunswick* the woods and plantations cover a surface of near 300,000 acres. *Saxony* is also abundantly supplied with forests and plantations. *Hesse Cassel* has about a million of acres of wood, and the Rhenish provinces are amply furnished with it. *Prussia* possesses about 18 millions of acres of woodland. Near Kunnersdorff is a wood 20 miles in length. The banks of the Oder are well furnished with fine oaks, as also pines, birches, and willows, of extraordinary dimensions; elms do not thrive. In several places the roads for miles are bordered with poplars, and there is abundance of flourishing plantations. *Bohemia* possesses forests of all the trees common in Germany; they are regularly cut, and furnish upwards of 270 millions of cubical feet of wood, of which, as it greatly exceeds the consumption of the country, a considerable part is exported. *Bavaria* grows a quantity of fine oak and beech timber: the principal forests are those of Spessart, the Rhon Gebirge, Zwieslar, Mitten, Kulwald, Retzler, Lorentz, &c.; they cover together a surface of upwards of seven millions of acres, being about 29-hundredths of the whole superficies of the country. In *Wurtemberg*, the forests occupy about one-third of the whole surface. *Baden* counts about two millions of acres of forests, consisting of oak and pine. In the *Archduchy of Austria*, though there are many forests, they have been so long neglected, that wood is comparatively scarce and dear. The *Hungarian states* have, towards the north and west, as also in Transylvania, some very extensive forests: that of Bakony, the most considerable in the country, is full of the finest oaks. The plains are in general bare of wood, but the Carpathians are covered with the dwarf pine (*Pinus pumilio*). The whole country contains about 12 millions of acres of forest. The *Tyrol* abounds in timber, of which a quantity is exported to Venice.

Switzerland is abundantly wooded, particularly with the cone-bearing trees. Oaks are found occupying a region which rises to the height of 2800 feet above the sea, beyond which, and to the height of 4000 feet, there are beech woods; the firs are found at the height of 5500 feet.

France has many fine forests, though hardly sufficient for the consumption of a country where wood is the chief combustible (and indeed is protected as such in the interest of the forest proprietors, to the detriment of the extraction of mineral fuel), and where the state of the arts and general civilisation create a constant demand for large timber and wood of every kind. The variety of climate and position in that country are however favourable to the growth of all kinds of European and many exotic trees; the oak, the birch, the elm, the ash, and the beech, are abundant; the elder grows in the damp places, and the mountains are clothed with pines and fir. The woods are pretty generally distributed over the country; and of the 86 departments into which the country is divided, there are 24, in each of which there are from 100,000 to 200,000 acres of wood, a dozen more containing from 200,000 to 300,000 acres, 6 having from 300,000 to 400,000 acres, and 3 which reckon each above 400,000 acres. The department of Dordogne alone contains upwards of 1,000,000 acres of wood. In all France there is reckoned about 21,000,000 of acres of woods and forests; of which about one-seventh, consisting of 1473 different forests, belong to the state.

Italy, the geographical position and local peculiarities of which are favourable in a high degree to vegetation of every kind, is not particularly rich in forest trees. There is at Ravenna an extensive forest of the stone pine (*Pinus pinea*). The Apennines also have their portion of coniferous trees, and are in some places covered to the top with luxuriant forests of chestnut-trees. The fertile basin of the Po abounds in plantations of olive, mulberry, fig, and almond-trees, while the pyramidal poplar forms a contrast by its tapering form with the flattened and branchy head of the stone pine; and the same may be said of other parts of Italy. In *Sicily* the forests have long since been exhausted, and wood is extremely rare in that island. But in *Sardinia* one-fifth of the surface is covered with ancient forests of oak, among which is the cork oak (*Quercus suber*), the common oak (*Q. robur*), and the evergreen oak (*Q. ilex*).

Spain and Portugal are deficient in wood, both as regards quantity and quality. The peninsula however is not unfavourable to the growth of timber; in the time of the Moors, the southern provinces in particular possessed some noble forests, but they have long since been devastated; and although since the time of Philip II. there has existed an excellent code of forest laws, they are altogether disregarded or evaded. Nevertheless there are still some forests in Spain; thus between the two Bagnères, in the Spanish valley of Aran, and on both sides of the western Pyrenees, there are forests of the silver fir; and on the south side of these mountains, east of Benasque, as also near Mont Pedru, and on the hills surrounding Andorra, are woods of the *Pinus uncinata;* and in the neighbourhood of Campo, in Upper Aragon, are forests of the *Pinus pyrenaica,* or, according to some, the *P. Larichio*, or Corsican pine. On the Sierra de Cuença, the Sierra de Segura, the Nevada, and the Serrania de Ronda, are some tracts of different kinds of pine, as the *P. Hispanica*, or Spanish pine (*P. halepensis*). The Aleppo pine grows in considerable quantities in Catalonia, and in the western part of Andalusia is a forest of the stone pine. The principal forest of Spain however is that of St. Ildefonso, which is chiefly of the Scotch pine (*P. sylvestris*). In the maritime part of the

Basque provinces there is nothing but the miserable *pin des landes.* In Biscay beech only is cultivated; but in Galicia and in Catalonia there are both oak and beech. In Estremadura there are forests of the evergreen oak, which produce the sweet or edible acorn; Catalonia, Valencia, and the environs of Seville, produce the cork-tree (*Q. suber*). This tree, which was formerly abundant in Andalusia, is proceeding rapidly to extinction. Many parts however of the Castiles, Aragon, Andalusia, and Estremadura, are without wood; and although the common oak is found in small quantity in the northern provinces, upon the whole there is a great deficiency of useful wood: all the middle and southern regions hardly produce one good kind of timber.

European Turkey—Of this country it is observable that, on the northern side of the Balkan, in the basin of the Danube, there are fine forests of oak, elm, and pine, and in Wallachia there are whole forests of fruit trees, particularly plum, apple, pear, cherry, and apricot. On the southern side of the chain the forests are particularly varied. Different kinds of pine and fir, oak, maple, sycamore, walnut, chestnut, and beech, are found in succession on the several terraces, while on the mountains themselves forests of oak, elm, and lime, abound. The Morea produces the cork tree, the Kermes oak, the Valona oak, of which the acorns are eaten, the plane, the wild olive, the sweet chestnut, the manna ash, pine, firs, and the larch, the barren date tree, the silk tree, &c., and a variety of plants used in the arts, and in pharmacy.

Russia.—Of all the countries of Europe, Russia is the most abundantly provided with timber; and her forests would be an almost inexhaustible source of wealth, if it were possible for the government effectually to protect them from destruction. In 1802 regulations for the preservation of the forests were established, but such is their extent and that of the country, that it is next to impossible wholly to prevent the waste of wood.

Hermann's 'Statistical Notice of the Agriculture of Russia,' published in the 8th vol. of the 'Memoirs of the Academy of Sciences of St. Petersburg,' and quoted in Mr. Schnitzler's work, states, "there are still 200,000,000 of acres exclusively covered with pine and other cone-bearing trees, without counting oaks, maples, beech, poplar, and hornbeam (none of which are scarce below the latitude of 52°), and birch, which grows further north." In the year 1804 it was estimated that there existed 8,192,295 pine trees fit for masts, being 30 inches in diameter; and 374,804 oak trees, of 24 inches and upwards in diameter; about 87,000,000 more pines were proper for building timber. Enormous as this may appear, the statement, so far from being exaggerated, would seem to be considerably below the truth, it being certain that in the three northern governments alone of Wologda, Archangel, and Olonetz, there are 216,000,000 of acres of forest trees, chiefly pine and fir. Birch, pines, fir, and limes, are the common forest trees of European Russia. The first is the most abundant as far as the 55th parallel, beyond which there are still found vast forests of pine and fir. The governments of Novgorod and Twer are covered with wood; the Volkonsky forest is the largest in Europe. In the government of Perm, of a surface of 50,000,000 of acres, 47,000,000 are covered with forests. Many of these immense tracts of wood are impenetrable, and harbour great quantities of bears, wolves, and other savage beasts, while others abound in deer and game of all kinds. In Esthonia, Livonia, and Courland, there are fine forests of pine, fir, and birch, the latter predominating in the moist places; alder, ash, elm, and plane, are found in the good soils, but oak is in general scarce. In Courland lime is abundant, but beech is rare; there are willows of several varieties. In general it may be observed that, in Russia, the pine, fir, and other coniferous trees, are found as far north as 57°; birch, aspen, and extensive forests of lime, as far as 54° or 55°; oak, rare in the central plateau, prospers towards 51° or 52°, but in the valley of the Volga they are fine and abundant at 55°. In the same region where the oak succeeds the Russian maple (*Acer tartaricum*) is in abundance, as also white poplar and hornbeam. In the central provinces beech hardly reaches Smolensk, and does not pass beyond Little Russia. In some parts of the Ukraine are fine oak forests. In Lithuania the timber is generally fir, intermixed with pine and birch, and occasionally oak. The woods of the latter province harbour bears, elks, &c., and in the celebrated forest of Bielovieje is found the aurochs, a species of wild ox, now peculiar to this locality.

Poland, generally speaking, is covered with magnificent forests; in Mazovia particularly there are some very fine woods. The different varieties of the pine are found in the sandy places, and on the mountains are fir and beech. Oak succeeds well in good soil. In addition to these trees Poland also possesses larch, lime, elm, and ash. In the Buckowine are forests of beech, intermixed with fir and birch woods.

It appears then, that although the progress of civilisation and increase of population have greatly diminished the forests which at one time covered great part of Europe, there is still an immense quantity of wood, and the necessity of keeping up a constant supply being now very generally acknowledged, there is reason to hope that the forests will no longer be abandoned to wanton destruction, but that, on the contrary, the felling of timber and cutting of copse woods will be properly regulated, and fresh plantations made to replace the wood consumed.

We will now take a hasty glance over other parts of the world.

Asia.—In the Caucasus we find that on the western, eastern, and southern slopes of this chain, there are forests of cedar, cypress, juniper, beech, and oak, and on the edges of these, quinces, wild apple, and pear trees; while the warm and sheltered valleys produce the almond, the peach, and the fig. On the borders of the Caspian there are woods of olive, plane, and laurel.

In *Asia Minor*, Mount Taurus is covered with forests of cypress, juniper, and savines. The gall-nut oak grows from the Bosphorus to Syria, and the Persian frontier; oaks and fir abound in the forests along the Black Sea. There are also in different parts woods composed exclusively of fruit-trees. Syria, to a vegetation greatly similar, adds the sycamore and palm trees.

Arabia has no forests, properly speaking. The oases, however, contain groves of date palms, tamarinds, and different fruit trees. In Hejaz the date palm is abundant.

Persia.—In Mekran there are forests of the Indian palm, intermixed with the odoriferous shrubs of Arabia Felix. In the valley of Shiraz we find only clumps of plane trees, weeping willows, and poplars; but the mountains which border the Caspian are covered with oak, lime, acacia, and chestnut: and higher up cedar, cypress, and other pines, with the sumach and the mountain-ash. Ghilan abounds in boxwood, and on the south-east of the Caspian there is great abundance of oak, but no pine.

Siberia is too cold for the oak, the hazel, the alder, the plane, and the wild apple; even the ash ceases towards the Irtish; and the fir, which in Norway grows as far as 70°, stops in Siberia at 60°, while the silver fir goes no further than 58°. The great steppes of this country are nevertheless bounded by thick forests of birch, willow, elm, Tartarian maple, black and white poplar, aspen, and a great variety of firs, among others the Siberian cedar, which sometimes attains a height of 120 feet, and is particularly fine on the banks of the Yenesei. The country between this river and the Baikal is well wooded. At Tobolsk are fine woods of birch, and of the pitch pine. Berezoff has also forests of birch and fir, with stunted Siberian cedar. In the government of Tomsk there are forests of elm, larch, willow, and birch; and between the Obi and the Tom, the land is covered with birch. To the west of Irkutsk the country is nothing but one vast, dense, and swampy forest. At Nertchinsk, in Russian Daturia, forests abound formed of larch, black and white fir, Siberian cedar, and black birch, which latter is found only here. There are also whole forests of wild apricot and rhododendrons. At Ockhotsk there are immense tracts of swampy forests, and Kamtchatka, the eastern limit of the Old World, abounds in larch, white poplar, and birch. The willow and the alder are employed only for fuel. On the whole, Siberia, notwithstanding its immense steppes and marshy plains, still reckons upwards of 2,000,000 of acres of forest in the two neighbourhoods alone of Ekaterinbourg and Tobolsk.

Central Asia is too little known for us to speak with any certainty regarding the forests it may contain. The greater part of the vast plateau of Tartary is a sandy and desert region, except at the immediate borders of the water courses; what forests do exist are on the slopes of the mountains by which the plains and valleys are surrounded. In the province of Leao Tong, in Manchuria, there are some extensive forests of fir, cypress, acacia, willow, apricot, peach, and mulberry, and on the east coast the mountains are covered with oak and pine, while towards the lower lands the willow, the maple, and the azalea are abundant.

Corea has immense forests in the mountains of its northern parts. The islands of *Sagalhin, Jesso,* and *the Kuriles* have large forests of the finest timber.

The *Empire of Japan* has a vigorous vegetation, partaking of the European and South Asiatic; larch, cypress, and weeping-willow, which, by the way, is found in all the temperate countries between the Mediterranean and this empire, are here blended with the cocoa-nut, the fan-palm, and arborescent mimosas.

China.—On the mountains of the western district of this great and populous empire there are forests of immense extent, abounding in almost every species of tree known in Europe, and many others unknown. These forests, besides timber and fuel, supply many valuable productions, such as barks, gums, oils, and resins used in the arts; rosewood, ebony, sandal-wood, and the valuable Chinese aloe; a camphor-tree, which furnishes the best and most beautiful timber, the paper and other mulberries, the tallow-tree, the bamboo, &c. The provinces of Kiang-si and Quang-si have also their mountains covered with forests, and in the latter province there is cinnamon superior to that of Ceylon.

The islands of *Formosa* and *Hainan* are abundantly wooded, producing, besides timber, several woods remarkable for their perfume, and others of great value for carving, as eagle-wood, violet-wood, and a yellow wood of remarkable beauty, said to be incorruptible. Returning to the continent of Asia, we find

Tibet, having the bases of its mountains girded with forests of bamboo, aspen, birch, cypress and yew, and ash of remarkable beauty; pine and fir are low and stunted.

Cashmere has abundance of oak.

India, both within and beyond the Ganges, is rich in wood. There are whole forests of the bamboo, which sometimes attain a height of 60 feet. Cocoa-nut and palms of all kinds cover large tracts. Here are woods of oak, fir, cypress, and poplar; there are mangoes, banian-trees, uvarias, robinias, sandal-wood, &c. Guzerat, Oudepoor, the kingdom of Asam, Bengal (along the coast particularly), the mountains of Tipra, and Malabar, abound in wood: the latter produces teak. In the Birman empire there are magnificent forests of the last-named valuable tree, together with white sandal-wood, eagle-wood, iron-wood, ebony, sycamore, Indian fig, fan-palms, bignonias, coccas, and sago-palms; as also fine groves of orange, lime, &c.

The mass of the forests of the Sikkim Himalayas, according to Dr. J. D. Hooker, commences at about the height of 5000 feet, where the agriculture of the country terminates in ascent; and is formed of—(1) three species of oak, of which *Q. annulata !*, with immense lamellated acorns, and leaves 16 inches long, is the tallest and the most abundant; (2) Chesnut; (3) *Laurineæ* of several species, all beautiful forest trees, straight boled and umbrageous above; (4) Magnolias. Many species of *Magnoliaceæ* (including the genera *Magnolia*, *Michelia*, and *Talauma*) are found in Sikkim. *Magnolia Campbellii*, which grows at 10,000 feet elevation, is the most superb species known. "In books on botanical geography," Dr. Hooker remarks, "the magnolias are considered as most abounding in North America, east of the Rocky Mountains; but this is a great mistake, the Indian mountains and islands being the centre of this natural order." (5) Arborescent rhododendrons, which commence here with the *R. arboreum*. At 8000 and 9000 feet of altitude a considerable change is found in the vegetation, the gigantic purple *Magnolia Campbellii* replacing the white; chesnut disappears, and several laurels: other kinds of maple are seen, with *Rhododendron argenteum* and *Stauntonia*, a handsome climber, which has beautiful pendant clusters of lilac blossoms. At 10,000 feet, as exemplified on the top of the mountain called Tonglo, a great number of additional species of plants are found, and all betoken a rapid approach to the alpine region of the Himalaya. In order of prevalence the trees are,—the scarlet *Rhododendron arboreum* and *R. barbatum*, as large bushy trees, 30 to 40 feet high, both loaded with beautiful flowers and luxuriant foliage; *R. Falconeri*, in point of foliage the most superb of all the Himalayan species, with trunks 30 feet high, and branches bearing at their ends only leaves 18 inches long. Next to these are shrubs of *Skimmia Laureola*, *Symplocos*, and *Hydrangea*, and still a few purple magnolias, very large *Pyri*, like mountain ash, and the common English yew, 18 feet in circumference. A currant is common, always growing epiphytically on the trunks of large trees. Two or three species of Berberry, a cherry, *Andromeda*, *Daphne*, and maple, nearly complete, in Dr. Hooker's opinion, the list of woody plants. The rarity of Pines is perhaps the most curious feature in the botany of Tonglo, and on the outer ranges of Sikkim; for, between the level of 2500 feet, the upper limit of *P. longifolia*, and 10,000 feet, that of the yew, there is no coniferous tree whatever in Southern Sikkim. ('Himalayan Journals,' vol. i., pp. 162–169.)

In some parts of India the entire destruction of the forests has rendered the country liable to the dreadful calamities which follow a deficiency of rain. The north-west provinces were denuded of their trees during the wars that attended the decline and fall of the Mohammedan empire and the rise and progress of the Jâts, Sikhs, and Mahrattas. These lawless freebooters swept away all the groves from the face of every district they invaded, whilst they never thought of renewing them, or encouraging their renewal, in those countries which they permanently occupied. Many fertile regions were thus turned into dreary and arid wastes. For many years past, however, the attention of the Indian government has been given to the protection and renewal of the forests, which are now committed to a special class of officers.

Ceylon is also well wooded with Asiatic trees and shrubs: among the former are the ebony and satin-wood, and of the latter the cinnamon is the most remarkable.

The kingdom of Laos, Tonquin, Cambodia, Siam, and the peninsula of Malacca, have a nearly similar vegetation. Of the kingdom of Cochin-China, including Tonquin, Cambodia, and Cochin-China Proper, it may be said that all parts produce good timber, including, according to Loureiro, teak. The other vegetable products of the forests of Cambodia in particular, which are applied to use, are Cardamoms, Agila or eagle-wood, gamboge, and stick-lac. The Siamese forests also produce teak (north of lat. 16°) and eagle-wood, together with sappan-wood (*Cæsalpinia sappan*), a kind of red wood, called by the resident Portuguese "Pao-rosa," or rose-wood; and a kind of benzoin, differing from that of Sumatra, more abundant, but inferior in quality; and two species of cardamomum, seemingly different from the *Amomum cardamomum* of Malabar. In various parts of the kingdom, especially of its southern districts, the tree or trees yielding gutta percha have been discovered, and the produce exported. The peninsula of Malacca, though luxuriant in vegetation, is on the whole inferior in products to the countries just noticed. There are many species of forest-trees, but not one is fit for the higher purposes of ship-building; teak does not exist; and about six only yield good durable timber. Sappan and eagle-wood again occur, together with ebony, but none of them in much abundance or of the best quality. The most valuable and remarkable product is gutta-percha. [GUTTA-PERCHA.]

Borneo is covered with a rank verdure, or a primeval forest of gigantic trees; the cleared and reclaimed spots forming but exceptional specks in this wild and unvaried landscape. The commercial products are benzoin, eagle-wood, camphor, the sago-palm, and ratans.

The *Philippine Archipelago*, embracing about 16° of latitude and 9° of longitude, and those between the 5th and the 21st degree of latitude north of the equator, is necessarily rich in products of all the kingdoms of nature. No fewer than 218 forest trees, chiefly of the more northern provinces, have been subjected to experiments in the arsenal of Manilla, and the relative strength, tenacity, and specific gravity of the timber ascertained for economic uses. In the most southerly island, Mindano, among many unknown forest-trees, we find the well known teak (*Tectona grandis*), this being, except Java, the only island of the Malay and Philippine archipelagos that is known to produce it in any considerable abundance; while Sumbawa is the only other island of the former in which it is known to occur at all. The intermediate islands of Bali and Lombok do not produce it.

Of *Oceania* it is sufficient to say, that all the islands are more or less abundantly covered with timber; many produce trees of immense size and of the finest wood.

"The whole island of *New Guinea*," or Papua, says Mr. Crawfurd, "so far as it has been seen, is one uniform and luxuriant forest, many of the trees of which run up to the height of 150 and 180 feet. The economical use of the timber of these huge trees has not been determined; but the forests of New Guinea produce three plants which have been immemorially in demand by the nations of the Malayan islands; namely, the true nutmeg (*Myristica moschata*), the missoy, or masui (*Cortex oninus*), and the pulasari (*Alyxia stellata*). If the timber should prove to be of good quality it is probable that it may come to be in demand with the European colonies of Australia, when these attain a dense population."

Australia, from its great extent, varies greatly in its flora. The forests in parts are extensive, and the pine, the iron wood, and mahogany, make good timber; but of many, such as the various species of Eucalypti, the wood is brittle. Many of the native trees are, however, useful for building or other constructive purposes.

New Zealand abounds in forests. The trees and ferns, indeed, give the distinguishing feature to the vegetation. In England, out of about 1400 species of plants, there are not more than 35 native trees. In New Zealand, of flowering trees, including shrubs above 20 feet high, there are upwards of 113, or nearly one-sixth of the flora, besides 156 shrubs and plants with woody stems. Dr. J. D. Hooker thinks that the *coniferæ* will prove, eventually, to be the most prevalent natural family of plants in the islands. The Kauri pine (*Dammara australis*) is not found south of Kawia, on the western coast, and the Bay of Plenty on the eastern. It is confined to the vicinity of the sea, but prefers sheltered localities. The Kauri forest forms a very deep deposit of turfy soil, which, being intermingled with much resinous matter, burns with great facility when dry. The resin of this pine is an important article of commerce with England, and the United States of America. The tree attains the height of 200 feet, and yields an invaluable light compact wood, free from knots, from which the finest masts for ships are now prepared.

Africa.—In spite of the burning heat of a vertical sun, there are in Africa spots which, by reason of their elevation or their proximity to the sea, enjoy a more temperate climate and abundance of moisture. In these places vegetation is rich beyond description. Thus Senegambia, Guinea, and Congo are covered with forests, which consist of the baobab (of which there are different kinds), of palms, robinias, sycamores, sandal-wood (red and gray), and tamarinds, intermixed with bananas, oranges, limes, and pomegranates; there are also cocoa-nut trees in great abundance. The tamarind and cedar, which grow in the greatest profusion on the borders of the Congo, furnish timber of the finest quality. *Abyssinia* has abundant woods, in which grow the smooth-leaved coral-tree (*Erythrina corallodendron*), the tamarind, the date, some mimoseas, and a large timber-tree which Bruce calls *rak*. On the coast of Adel there are odoriferous forests, producing the balm of Judæa, myrrh, &c. *Egypt*, though abounding in plantations of fruit-trees and dates, has no forests. The Atlas Mountains, on the contrary, are covered with magnificent forests, and producing a variety of oaks, the mastic tree, the cypress, &c. In the interior of the Atlas, the environs of Borgou are said to be covered with trees, among which are several kinds of sycamore, palms, and the *Mimosa nilotica*. The kingdom of Bornou has immense forests, and the date-palm abounds here. *The Cape*, celebrated for the beauty of its vegetation, was generally thought to be deficient in forest-timber, but it has been discovered that to the eastward there are forests of the finest oak of the Albanian kind, celebrated for its quality and durability. These forests also produce iron-wood, the sago-palm, &c.; as yet, however, they have been but imperfectly examined. Of the African islands, *Madagascar* is rich in timber, and a variety of woods useful in the arts. The same may be said of the islands on the west coast; they are generally well wooded.

In a general survey of the globe, we may look upon the New World as pre-eminently the land of forests (as will appear when we come to treat of the forest of the Amazon), contrasting strongly with the Old World, where steppes and deserts are the most characteristic features. This fact is probably related to a great element in the chronology of physical geography,—the comparative youth of America (thus new as a part of nature as well as to knowledge) in the present geological period of the earth. The oldest sedimentary formations, the Silurian, Cambrian (and perhaps the more recently recognised Laurentian), strata, appear to be universal; but the periods when they constituted the surface of the land, with their clothing of vegetation and population of animals, belong to the most remote physical antiquity. As land of the present period, with its appropriate organic beings of both kingdoms, of the present period also, including man himself, the great continent of Europe, Asia, and Africa, would appear to be the oldest; America, as a country of the present period, seems to have been produced and peopled next; while Australia, together with the eastern portion of the Indian Archipelago (which, as very recently shown by an accomplished traveller and naturalist, Mr. Alfred R. Wallace, belongs to the same natural region), forms a still newer world. The differences with respect to the association of plants which produces what we term forests, and to vegetation in general, between Australia proper and America, are no doubt dependent principally on the peculiarities of climate of the former, which have already been noticed in the article DESERTS.

America, accordingly, is, of all parts of the world, the most thickly covered with wood. Beginning with the north, we find the Russian territory on the north-west coast abundantly stocked with fine timber: pines 300 feet high and 45 feet in circumference, Canadian poplar, alders 40 feet high below the branches, birch, yew, black and common oak, American ash, sycamore, sugar maple, cypresses 24 feet in circumference, and willows. The islands on this coast have also magnificent forests of pine and other lofty trees.

In *New Britain* the forests are extensive, but they present little variety, and in some parts, to the northward particularly, the larches and birches are stunted in their growth. The environs of Lake Winnipeg are covered with the trees common to Canada.

In *Greenland* there are only a few stunted willows and birches; and *Labrador* has merely some pines and pinasters in the valleys.

Canada contains immense forests. Pines and evergreens are the most abundant, after which come the red and the sugar maple, the birch, the lime, the American elm and iron-wood, the yew, the common and mountain-ash; also a great variety of oaks, different from the European species, which do not thrive here.

New Brunswick has large forests of fine timber, particularly pine, which it exports.

Nova Scotia produces good oak; but the principal wood is pine, fir, and birch.

The island of *Cape Breton* furnishes immense oaks and magnificent masts. *Newfoundland*, and the other islands at the mouth of the St. Lawrence, also produce timber fit for naval and other constructions.

The *United States* are abundantly wooded, the cleared land even in some of the Atlantic states being inconsiderable when compared with that still covered with the primitive forests, which contain an immense variety of trees. There are about forty different kinds of oak, fourteen of pine, besides cedar, cypress, and larch; several maples, among which is that from which sugar is obtained, birch, ash, beech, iron-wood, hornbeam, hickory, wild cherry, and apple, mulberry, poplar, willow, magnolias, elm, chesnut, &c. Of all the states, Ohio perhaps contains the finest forest-trees. The woods of Florida present a mixed vegetation, exhibiting the productions of both the north and the south. Thus there is red and white pine, evergreen oaks, chesnut, mahogany, walnut, cherry, maple, logwood, Brazil-wood, and sassafras. There are also in Florida whole forests of red and white mulberry, the finest in America. All European fruits also grow here, and the oranges are finer than in Portugal. In California the pine attains an enormous growth, and the timber has been found to be of excellent quality. The Oregon territory and British Columbia are both well wooded.

In *Mexico* or *New Spain* there are abundant forests, differing in character according to their position on the heights or in the plains. In Texas there are great plains covered with palms, while the heights are clothed with the timber-trees of Louisiana. The mountains in the neighbourhood of Guanaxuata and Valladolid are covered with forests, and the Intendance of Mexico abounds in cedar and other large trees.

Yucatan is famous for its logwood and mahogany; the latter is also produced in great abundance round the *Bay of Honduras*.

Nicaragua has groves of palms which attain an immense magnitude; and in *Costa Rica* and *Varaguay* there is fine forest-timber.

The *West India Islands* generally abound in wood, though there are exceptions.

In *South America* the Caraccas possess inexhaustible forests, which, besides the finest timber, produce also a great variety of beautiful woods for cabinet-work, dye-woods, drugs used in the arts, and medicinal plants, as the sarsaparilla, bark, &c.

In *New Grenada* the plateau of Bogota, Popayan, and Pasto have fine forests. The neighbourhood of Guayaquil, besides the common timber of the country, possesses a wood remarkable for strength and solidity, which is said to be incorruptible, and to resist worms better than any other; qualities which render it invaluable for the keels and ribs of vessels.

Peru is rich in forests, which furnish timber, gums, resins, dye- and cabinet-woods, all of the finest quality.

Chile possesses forests of gigantic trees, many of incorruptible wood, and others useful for their gums, resins, &c. Pines and cedars are abundant. The whole chain of the Andes abounds in wood, varying in kind according to height, latitude, and aspect. The vigour of the vegetation in some parts is inconceivable: thus in Chile trees have been found so large, that an entire church, 60 feet long, with all its wooden appurtenances of doors, windows, &c., has been built of a single tree.

The *Magellanic Lands*, on the west or mountainous part, contain forests.

Paraguay is rich in wood, on the borders of the Upper Uraguay; and, among other trees, produces in abundance that from which the resin termed dragon's-blood is obtained.

Brazil contains extensive forests, which cover immense tracts, and are composed of palms, Brazilian cocoa, loftier than the Indian, together with an endless variety of other trees peculiar to the country: some of these are of extraordinary size. The Brazilian pine furnishes very fine masts: this country exports a large quantity of timber, and supplies all the Portuguese shipping. Brazil also produces the dye-wood which bears its name.

Guiana has extensive forests in its higher parts; but the wood of many of the trees is so soft as to be only good to burn, and that of others is too hard to be worked. It produces many dye-woods.

The forest-region of the river Amazon and of the upper Orinoco, according to Humboldt, covers an area of about 719,000 square miles.

The entire extent of the valley of the Amazon, with the exception of some very small portions, is covered with one dense and lofty primeval forest, the most extensive and unbroken which exists upon the earth. It is the great feature of the country,—that which at once stamps it as a unique and peculiar region. Here we may travel for weeks and months inland, in any direction, and find scarcely an acre of ground unoccupied by trees. It is far up in the interior where the great mass of this mighty forest is found; not on the lower part of the river, near the coast, as is generally supposed. A line from the mouth of the river Parraiba, in long. 41° 30′ W., drawn due west towards Guayaquil, will cut the boundary of the great forest in long. 78° 30′, and, for the whole distance of about 2600 miles, will have passed through the centre of it, dividing it into two nearly equal portions. For the first 1000 miles, or as far as long. 56° W., the width of the forest from north to south is about 400 miles; it then stretches out both to the north and south, so that in long. 67° W. it extends from 7° N., on the banks of the Orinoco, to 18° S, on the northern slope of the Andes of Bolivia, a distance of more than 1700 miles. From a point about 60 miles south-east of Tabatinga, a circle may be drawn of 1100 miles in diameter; the whole area of which will be virgin forest.

"The forests of no other part of the world," observes Mr. A. R. Wallace, from the scientific additions to whose 'Travels on the Amazon and Rio Negro' we derive these corrected particulars of the forest-region of the Amazon, "are so extensive and unbroken as this. Those of Central Europe are trifling in comparison; nor in India are they very continuous or extensive; while the rest of Asia seems to be a country of thinly-wooded plains, and steppes, and deserts. Africa contains some large forests, situated on the east and west coasts, and in the interior south of the equator; but the whole of them would bear but a small proportion to that of the Amazon. In North America alone is there anything approaching to it, where the whole country east of the Mississippi and about the great lakes, is or has been an almost uninterrupted extent of woodland."

The forests of the Amazon are distinguished from those of most countries by the great variety of species of trees composing them. Instead of extensive tracts covered with pines, or oaks, or beeches, we scarcely ever see two individuals of the same species together, except in certain cases, principally among the palms. A great extent of flooded land about the mouth of the Amazon is covered with the Miriti Palms (*Maurititia flexuosa* and *M. vinifera*), and in many places the Assai (*Euterpe edulis*) is almost equally abundant. Generally, however, the same species of tree is repeated only at distant intervals. On a road for ten miles through the forest near Pará, there are only two specimens of the Masserandúba, or Cow-tree, and all through the adjoining district they are equally scarce. The *Leguminosæ* are by far the most abundant species among the forest-trees of the Amazon.

The following list of the principal vegetable productions of the Amazon forests is given by Mr. Wallace:—"India-rubber, from the sap of the *Siphonia elastica*; Brazil-nuts, the seeds of the *Bertholletia excelsa*; Salsaparilha, the roots of *Smilax syphilitica*; Tonquin-beans, the seeds of *Dipteryx odorata*; Puxiri, the fruit of *Nectandrum puchury*; Sassafras oil, tree not known; Andiroba oil, from the fruit of an unknown tree; Crajuru, a red colour prepared from the leaves of *Bignonia chica*; Pitch—exudes from a forest tree; *Cacao*, the seeds of *Theobroma cacao* and other species; Cravo, from an unknown tree; Canella, the bark of *Canella alba*; Vanilla, the fruits of various species of *Vanilla*; Guaramá, a preparation from a fruit, grated in water, to form an agreeable and medicinal drink; Piassába, the fibres from the petioles of a palm, *Leopoldinia*, n.s.; *Balsam Capivi*, from the *Copaifera officinalis*; Silk-cotton, from various species of *Bombax*."

From the above rapid sketch of the forest-lands of the globe, it appears that they still cover a great portion of its surface, nor can it be doubted that the immense tracts of wood we have enumerated exercise a very powerful influence on the physical economy of the earth. This influence is both direct and indirect. The direct influence of forests is the diminution of temperature, effected, according to Humboldt,—"1, By screening the soil from the heat of the sun's direct rays; 2, by the powerful evaporation of moisture from the leaves; and 3, by the immense surface which these same leaves offer to the cooling process of radiation."

The indirect influence is the preservation of that due circulation of moisture by which the fertilising rivers of the earth's surface are furnished with a perennial supply of water. Such, indeed, is the importance of forests in this respect, that if it were possible to annihilate at once all the forests that now exist, the earth would no longer be habitable. The rains which fall in the mountains, no longer arrested by the trunks and roots of the trees, would not have time to percolate through the soil and fissures of the rocks to supply the reservoirs of springs, but would pour down in devastating torrents, leaving the watercourses dry as soon as the rain had ceased. This, in a limited degree, has been already experienced in places where the heights have been partially denuded of their forests; and its effect on the rivers in some parts of the United States, where the portion of cleared land is considerable, is distinctly observed. Nor would this be all: lakes, for want of supply, would soon be dried up; and as no waters but those of the ocean would then exist, the atmosphere would then be deficient in moisture; no vegetation could exist, and the animal world would perish of thirst, hunger, and heat. Forests, then, are of primary importance in the economy of the globe, independent of their utility in a thousand arts which are necessary now to our comfort. This consideration has at length awakened governments to the necessity of protecting forests from wanton spoliation by codes enacted for the purpose, and of forming schools in which all that is necessary to be known for the management of forests, so as to maintain a constant supply of timber and fuel, shall be regularly taught. [FOREST SCIENCE.]

FOREST LAWS. In this country even in the time of the Saxons the crown lands consisted in part of forests, or tracts more or less covered with wood, in which the king was accustomed to take the diversion of hunting, and from hunting in which all other persons were prohibited. This distinctly appears from the laws of Canute. But the prohibition against hunting in the royal forests was merely a protection thrown around the property of the crown of the same kind with that afforded to all other landed estates, in regard to which, universally, the law was, that every proprietor might hunt in his own woods or fields, but that no other person might do so without his leave. On the establishment, however, of the Norman government the property of all animals of chase throughout the kingdom was held to be vested in the crown, and no person without the express licence of the crown was allowed to hunt even upon his own estate. This however, is rather a conjecture deduced from the supposed principles of feudalism, than a well-established fact. There are no laws respecting the forests among those attributed to the Conqueror; but after the conquest the forests were guarded with greater strictness; their number was extended and their bounds enlarged; trespasses were punished with greater severity; and, finally, a system of laws and of courts for their administration was established, by which not only all offences touching the royal forests were tried, but all persons living upon these properties governed. This is the system properly called the forest laws. Of this in its original integrity we have no complete or authoritative record: our knowledge is derived from incidental notices of the chroniclers; the energetic language of complaint and condemnation in which it is spoken of; the legislative enactments for its reform which have been preserved; and the remnants of it which survived to a comparatively recent period.

The Conqueror is said to have possessed 68 forests, 13 chases, and 781 parks. Forests and chases differ from parks in not being inclosed by walls or palings, but only encompassed by metes and bounds; and a chase differs from a forest, both in being of much smaller extent (so that there are some chases within forests) and in being capable of being held by a subject, whereas a forest can only be in the hands of the crown. The material distinction was, that forests alone were subject to the forest laws. Every forest however was also a chase. A forest is defined by Manwood, the great authority on the forest laws, as being "a certain territory or circuit of woody grounds and pastures, known in its bounds, and privileged, for the peaceable being and abiding of wild beasts, and fowls of forest, chase, and warren, to be under the king's protection for his princely delight; replenished with beasts of venery or chase, and great coverts of vert for succour of the said beasts; for preservation whereof there are particular laws, privileges, and officers belonging thereunto." The beasts of park or chase, according to Coke, are properly the buck, the doe, the fox, the marten, and the roe; but the term in a wider sense comprehends all the beasts of the forest. Beasts of warren are such as hares, conies, and roes; fowls of warren, such as the partridge, quail, rail, pheasant, woodcock, mallard, heron, &c. He afterwards however quotes a decision of the justices and the king's council that roes are not beasts of the forest, because they put to flight other wild beasts (eo quod fugant alias feras), which seems an odd reason; perhaps the word should be "fugiunt" (because they fly from other wild beasts). And he adds, "beasts of forests be properly hart, hind, buck, hare, boar, and wolf; but legally all wild beasts of venery." ('Co. Litt., sec. 387.)

For the antiquity of the royal forests in England, "the best and surest argument," says Coke, elsewhere (4 'Inst.' 319), "is, that the forests in England, being sixty-nine in number, except the New Forest, in Hampshire, erected by William the Conqueror, and Hampton Court Forest, by Henry VIII., and by authority of parliament, are so ancient, as no record or history doth make any mention of their history or beginning." Yet it appears, both from the great charter of John, and from a previous charter granted by Stephen, that some lands had been afforested (as the term was) after the time of the first two Norman kings. "The forests," says Stephen, "which King William my grandfather, and William II. my uncle, made and held, I reserve to myself; all the others which King Henry superadded I render up and concede in quiet to the churches and the kingdom." And one of the concessions demanded from John and granted in Magna Charta (§ 47) was, that all the lands which had been afforested in his time should be immediately deafforested. No additional forests appear to have been made from the reign of John till that of Hampton Court was constituted by act of parliament in 1539 (31 Hen. VIII. c. 5). The name given to it in the statute is Hampton Court Chase; but it is enacted that all offenders in it shall incur such penalties as the like offenders do in any other forest or chase. It was therefore made a forest as well as a chase.

Many historians tell us that King John granted a charter of forests at the same time with Magna Charta. This is indeed distinctly asserted by Matthew Paris, who even professes to give the charter at full length. But the statement is entirely unfounded; the concessions obtained from John in regard to the royal forests are, as mentioned above, contained in the Great Charter; the Carta de Foresta, which M. Paris quotes, is a charter granted by Henry III. in the 9th year of his reign (A.D. 1224). This was the first separate charter of forests. It is commonly printed in the statutes from the Inspeximus, or confirmation of it, in the 28th of Edward I. (A. D. 1299). The subsequent legislation upon this subject is principally to be found in the following statutes:—The Customs and Assize of the Forest, or the Articles of Attachments of the Forests (of which the date is not known); the Ordinatio Forestæ of the 33 Edw. I. (1305); the Ordinatio Forestæ of the 34 Edw. I. (1306); the 1 Edw. III. c. 8 (1327); and the 7 Ric. II. c. 3 (1383).

One of the chief things insisted upon in the early national demand for the reform of the forest laws, was the mitigation of their severe code of punishments. The Conqueror, who, as the 'Saxon Chronicle' says, loved the red deer as if he had been their father, is affirmed to have visited the slaughter of one of these animals with a heavier penalty than the murder of a human being. And it would appear from the charter of Henry III. that the offence had previously been punishable not only with mutilation, but with death. "No man from henceforth," says the charter, "shall lose either life or member for killing of our deer; but if any man be taken and convict for taking of our venison, he shall make a grievous fine, if he have anything whereof; and if he have nothing to lose, he shall be imprisoned a year and a day and after the year and a day expired, if he can find sufficient sureties, he shall be delivered; and if not, he shall abjure the realm of England." According to Matthew Paris (whose authority, however, on such a matter, is not worth much), Richard I. had already repealed the penalties of mutilation for offences against the forest laws.

The forest laws, as already mentioned, were administered by their own officers and courts. The officers were the justices in eyre of the forest [EYRE]; the wardens or warders; the verderers, foresters, agisters, regarders, keepers, bailiffs, beadles, &c. The courts were:—1. The Court of Woodmote, or of Attachments, sometimes called the Forty Days' Court, held once in every forty days before the verderers; 2. The Court of Swainmote, held three times in the year before the verderers as judges, and with a jury composed of the *swains*, or freeholders within the forest; and 3. The Court of Justice-seat, which was the supreme court, held every third year before the chief justice in eyre of the forest. This was a court of record, and, at least in later times, it was held that a writ of error lay from it to the Court of King's Bench. With the exception, however, of one said by Roger North in his life of Lord Keeper North to have been held *pro forma* soon after the Restoration, no court of justice-seat has been held since 1632. A minute survey of the forest was also taken every third year by its twelve regarders; and it was upon this occasion, and under the inspection of the regarders, that the lawing or expeditation of all the mastifs in the forest took place, which consisted in cutting off the claws and ball (or pelote) of their forefeet, to prevent them from running after the deer.

The four principal forests in England were accounted to be, the New Forest, Sherwood, Dean, and Windsor. Among the others were Epping, in Essex; Dartmoor, in Devonshire; Wichwood, in Oxfordshire; Salcey, Whittlebury, and Rockingham, in Northamptonshire; Waltham, in Lincolnshire; Richmond, in Yorkshire, &c.

The vexatious and oppressive powers vested in the crown by the forest laws, after having to a great extent long ceased to be exercised, were revived by Charles I., and endeavoured to be turned to account in replenishing his exchequer. At the court of justice-seat, held in 1632, before the Earl of Holland as chief justice in eyre south of the Trent, large sums of money were extorted from many persons, chiefly as compositions for alleged encroachments on the ancient boundaries of the forests, although after a quiet possession of three or four centuries. This accordingly was one of the grievances to which the Long Parliament directed its earliest attention. One of the Acts which that assembly passed in its first session (16 Car. I. c. 16), was entitled 'An Act for the Certainty of Forests, and of the Meets, Meers, Limits, and Bounds of the Forests,' and it enacted that the bounds of every forest shall be those commonly known, reputed, used, or taken to be its bounds; and that all judgments, &c., to the contrary shall be void; that no place where no justice-seat or other forest court had been held within sixty years should be accounted forest; and that commissions should be issued for ascertaining the bounds of forests as they stood in the 20th year of the preceding reign, and beyond which they should not thenceforth be extended. Since the passing of this Act, the old forest laws may be considered as having been practically abolished, and the offices connected with their administration and execution turned into little better than sinecures.

The Carta Forestæ of Henry III. contains the following curious provision:—"Whatsoever archbishop, bishop, earl, or baron, coming to us at our commandment, passeth by our forest, it shall be lawful for him to take and kill one or two of our deer, by view of our forester, if he be present; or else he shall cause one to blow an horn for him, that he seem not to steal our deer; and likewise they shall do returning from us as it is aforesaid." As this law is still unrepealed, any bishop or nobleman may shoot one or two of the deer if he should pass through any of the royal forests in going to or returning from parliament. Hunting, it may be observed, was formerly so common or universal an episcopal amusement, that the crown is still entitled, at the death of every bishop, to have his kennel of hounds, or a composition in lieu thereof. Auckland Park, and certain other demesnes, formerly held of the Bishop of Durham by forest services; "particularly," says Camden, "upon his great huntings, the tenants in these parts were bound to set up for him a field-house, or tabernacle, with a chapel, and manners of rooms and offices; as also to furnish him with dogs and horses, and to carry his provision, and to attend him during his stay for the supply of all conveniences. But now all services of this kind are either let fall by disuse, or changed into pecuniary payments." [Game Laws; Woods and Forests.]

FOREST SCIENCE, constitutes a separate and distinct branch of education, which orignated in Germany from the increased scarcity of wood. The first special instruction of this kind was given by Mr. Zanthier at Ilsenburg, near the Harz forest, and its importance being immediately appreciated, forest academies soon multiplied, particularly in the central parts of the country. Prussia directed particular attention to the subject, and the late king Frederick, on coming to the throne, ordered that, "in future, situations in the forest department should be conferred with a view to the most perfect preservation of the forests; that the nominations should be founded on knowledge and experience, and no longer granted as a recompense for service." In consequence a new organisation took place, and competent instruction in all things appertaining to the management of forests became a necessary qualification for an appointment to any post in the forest department.

In the forest academies are taught botany generally, and particularly as regards the ordinary productions of the forest, including vegetable physiology, mineralogy, zoology, chemistry, surveying, mensuration, mechanics, the methods of resisting the encroachments of sands, draining and embanking, together with the care and chase of game; as also the laws and regulations of forest administration. The examination which the candidates undergo is very strict, and the result of the system has been eminently beneficial.

France has also a particular administration of the forests, and a very detailed code of forest laws. Russia, from the immense extent of its forests, is under little apprehension of a scarcity of wood, nevertheless the consumption of this article is so enormous, all the houses of the peasantry being built of it, and no other fuel being used, that it has been deemed advisable to pay some attention to the subject, and a board has been formed under the particular sanction of the government for the better preservation of the forests and more general instruction in forest science.

Louis XIV., by an *ordonnance* of 1669, placed the forests under the direction of a separate branch of the government. Men of science then began to turn their attention to this subject. Du Hamel du Monceau and Buffon were among the first naturalists who wrote on the management of forest trees.

The consideration of the various trees which may be cultivated to advantage, and the uses to which their woods may be put, with the mode of their propagation in various soils, form a branch of forest science.

The following is a list of the principal forest trees:—

The oak *Quercus*), and its varieties, the beech (*Fagus sylvatica*), the hornbeam (*Carpinus betulus*), the birch (*Betula alba*), the elm (*Ulmus*), the maple (*Acer campestre*), the alder (*Betula alnus*), the ash (*Fraxinus excelsior*), the lime (*Tilia sylvestris*), the chestnut (*Fagus castanea*), the walnut (*Juglans regia*), the crab (*Pyrus malus*), the wild cherry (*Prunus avium*), the mountain service (*Sorbus aucuparia*), the service (*Sorbus domestica*), the aspin (*Populus tremula*), the white poplar (*Populus alba*), the common poplar (*Populus nigra*), the Lombardy poplar (*Populus fastigiata*), the sycamore (*Acer pseudo-platanus*), the plane (*Acer platanoides*), the hazel (*Corylus sylvestris*), the sallow (*Salix caprœa*), the osier (*Salix viminalis*), the pine (*Pinus sylvestris*), the silver fir (*Pinus picea*), the larch (*Larix Europea*). The wood of all those trees is divided into three sorts: hard wood, white wood, resinous wood. The German writers admit only two sorts of trees, the deciduous and evergreen, but this is more a botanical division than one applicable to forest-trees.

The uses to which the wood is applied vary very much, according to circumstances and situations. The most profitable is that of timber for buildings, and more particularly for naval architecture. The oak, beech, elm, and fir, are the chief woods employed for this purpose; but the chesnut was at one time considered as equal to the oak, as the roofs and beams of many old buildings testify; Windsor castle among the rest. For millwrights the ash, beech, service tree, walnut, and crab, are most useful. For various utensils for the dairy and domestic use, the sycamore, the lime, and the poplar, are used on account of the whiteness of their wood. Various soft woods are used for turning, as well as the hardest, when they have a close grain and are not apt to split.

When wood cannot be applied to building or domestic uses it is still very valuable as fuel, and in this point of view it is important in those countries where pit coal is not abundant. The best wood for fuel is oak, and next to this beech. The harder the wood, in general, the more heat it gives out in burning. The trunks of large trees, sawn into convenient lengths and then split into billets, make the best fuel; but where wood is scarce it is found most profitable to cut down the trees at the age of 30 or 40 years at most, when they have acquired a considerable height of stem but no great girth. In the woods which are planted for this purpose in France and Germany the trees are drawn up by being left close together, and the side branches are kept cut to the height of 30 or 40 feet, so that they only spread out at top, and the trunk never acquires the size which it would if the tree stood singly, and had room to spread out its branches.

In order to judge of the value of woods in different soils the following table may be useful. It is calculated on the supposition that the ground is covered with trees as much as it will bear.

The cord here alluded to is 5 feet 6 inches in height, 8 feet long and 3 feet 6 inches wide, French measure, that is very nearly 6 feet high 8 feet 8 inches long, and 3 feet 10 inches wide, or 200 cubic feet English measure.

In the following table the tops made into charcoal and the faggots are reduced to cords in the proportion of four and a half cords of charcoal-wood and 550 faggots for one cord of fire-wood.

Produce of Fire-wood per Acre, at different Ages, in Cords.

Age of Trees. Years.	On Poor Soils.	Middling Soils.	Good Soils.
10	2	3½	4½
15	2¼	5¾	9
20	3¾	9¼	15
25	5¼	13¼	21
30	6½	16¾	27
35	7	21	35
40	7	24½	42
50	6	31	56
60	5	37½	70
70	3	41½	80
80	2	46	90
90	1	48½	96
100	..	51	102
120	..	57	114
140	..	62	124
150	..	64	128
200	..	67	135
250	..	60	120
300	..	55	110

This table is the result of careful measurement of woods cut down at different ages; and it shows that the maximum in poor soils is attained in 35 years, in middling and good soils at 200. But it also shows that the increase of wood per cent. in ten years is greatest from 20 to 30 in poor soils, from 40 to 50 in middling soils, and from 70 to 80 in good soils: so that it never can be profitable to allow any wood which is to be used for fuel to stand above 80 years.

In good soils at thirty-five years growth the wood in the tree has increased one cord per acre each year; and the rate of growth increases till the nineteenth year, after which it begins to diminish. But it must also be taken into the account that wood of the age of 70, 80, and 90 years is of far greater specific gravity than that of 25 or 30; and consequently the increase in bulk in ten years, from 80 to 90, produces more fuel than the mere measure indicates. On good soils oaks and beech will continue to increase for 200 years; but in poor soils they do not thrive after thirty-five years, and then they begin to waste.

Preparatory to making a plantation of any extent it is necessary to establish a nursery to raise plants; for although trees which are raised from seed and have never been moved become much larger and finer than those which are transplanted, it will be found on calculation that a quick return is much more profitable; and as a matter of economy trees which have been raised in a nursery and transplanted arrive sooner at a certain growth than those which are sown on the spot where they are to remain.

The ground chosen for a nursery should not have a better soil than that in which the plants are finally to be placed, because, in that case, they would most likely suffer, if not perish altogether. The surface may be enriched by some manure to make the seed vegetate. If it is small, it may be sown in drills, and the acorns and larger seeds may be dibbled regularly as beans are in a garden. The ground being kept very free from weeds by hoeing, the plants will rise regularly, and they may be thinned out after the first year; those which are taken out may be transplanted after cutting off the tap-root, in another spot in the nursery. When the trees are three or four years old, and have clean and straight stems, the side branches having been carefully pruned off, they may be transplanted where they are to remain. The ground should be trenched and well drained if it is wet. It is useful in northern climates to plant hardy evergreens, such as the Scotch fir, amongst forest trees, to serve as shelter to them while they are tender. These are called nurses, and are generally cut out, as the oaks, ash, beech, and other more valuable trees grow up. If the ground is dry it is only necessary to dig a hole eighteen inches deep and a yard in diameter, for each tree; this is to be half filled up with the loose earth taken out; the young tree is then to be placed on this surface and its roots spread out, the tap-root being cut off. The best earth is then carefully spread over the roots and trod in with the feet, and the whole filled up to the level of the ground. In wet situations the trees are sometimes placed nearly on the surface of the ground, and a small mound of earth is raised round the stem; but it is much better to drain the land properly, without which the plantations will never thrive. The proper distance to plant oaks is ten feet apart each way with a fir-tree between every two. In five years half of the firs may be cut out, and the oaks pruned where it is necessary. In fifteen years all the firs will be cut out and the oaks will be able to protect one another. In twenty-five years from transplanting, half of the trees may be cut down, and the remainder thinned out gradually as they spread and advance in growth.

In England, where crooked pieces of large oaks are of value in ship-building, the side branches are not taken off higher than fifteen or twenty feet from the ground; and where trees have plenty of room, as in hedge-rows or parks, this may be judicious, but in close plantations it is of advantage to have a long stem without branches. Knee-timber, as it is termed, is however now much less in demand than formerly, on account of the method adopted of artificially bending straight timber for purposes of naval construction. In France and Germany the branches are always cut off to the height of thirty or forty feet. This is done gradually as the tree grows. When the branch is very young it may be cut close to the tree, and the bark will soon cover the wood and obliterate the scar. When they are larger, it is best to shorten them to a few inches from the stem the first year, and cut them close the next: when a branch is cut close in a young tree no portion of it must project beyond the wood of the stem, and if a portion of the bark of the latter is cut to make all smooth, it will be no detriment, and the wound will soon heal over provided it is done at the proper time. But if a large branch is cut so that the bark cannot grow over the wound in one year, there is great danger of causing a fault in the wood by the decay of the heart of the branch; in that case it is better to cut it at some distance from the trunk, and to shorten it repeatedly till the branch dies naturally and breaks off. In that case no flaw will be found in the wood. This is the operation of nature in a close wood, which we should endeavour to imitate.

FORESTALLING was, like engrossing, an offence at common law against trade. It is described in 5 & 6 Edw. VI. c. 14, to be the buying or contracting for any merchandise or victual coming in the way to market; or dissuading persons from bringing their goods or provisions there, or persuading them to enhance the price when there, any of which practices were supposed to make the market dearer to the fair trader. The prohibition seems to have been derived from the Roman law, which imposed a penalty of twenty pieces of gold in such cases. ('Dig.' 48, tit. 12. 2.)

The true principles of trade being now better understood, forestalling is no longer an offence.

FORFEITURE, the punishment by loss of lands, estates, rights, offices, or personal effects, annexed by law to certain crimes, and also to certain illegal acts or negligence in the holder of lands or offices.

In criminal cases forfeiture is threefold:—1. Of real estates absolutely, as for high treason; if freehold, to the king; if copyhold, to the lord. 2. Of the profits of the real estate, if freehold, to the crown during the life of the offender, and a year and a day afterwards, in the case of petty treason or murder [FELONY], after which the land escheats to the lord [ESCHEAT]; if it is copyhold, it is at once forfeited to the lord. 3. Of goods and chattels, in felonies of all sorts. Some other cases of forfeiture of land or goods, or both, are established by different statutes, as the statutes of premunire, &c.

Lands are forfeited upon attainder, and not before [ATTAINDER]; goods and chattels, upon conviction. The forfeiture of lands has relation to the time of the offence committed; the forfeiture of goods and chattels has not, and those only are forfeited which the offender has at the time of his conviction. A *bonâ fide* alienation of his goods and chattels made by a felon or traitor between the commission of the offence and his conviction is therefore valid.

The statute 15 & 16 Vict. c. 3, contains directions for keeping accounts, and for investment and disposition of forfeited property recurring to the queen by virtue of her prerogative.

Forfeiture in civil cases takes place where a tenant of a limited, or, as it is called, a particular estate, grants a larger estate than his own, as where a tenant for life assumes to convey the fee simple. So, if a copyholder commits waste, or refuses to do suit of court, or a lessee impugns the title of his lessor; for in all these cases there is a renunciation of the connection and dependence, which constitute the tenure, and which are an implied condition annexed to every limited estate.

Forfeiture may also be the consequence of the breach of express conditions or covenants between landlord and tenant, or persons connected in tenure; but in cases of forfeiture where compensation can be made for the breach of the condition, a court of equity will compel the party entitled to the forfeiture to accept compensation. The right to take advantage of a forfeiture may also be waived by any act of the person entitled which recognises the continuance of the title in the particular tenancy,—as, for instance, the receipt of rent by a landlord in respect of a time subsequent to the act by which the forfeiture is incurred.

Lands may also be forfeited by alienation contrary to law, as by alienation in mortmain without licence, or to an alien: in the former instance, if the immediate lord of the fee, or the lord paramount, neglect to enter, the crown may; and in the latter, though the conveyance is effectual, yet as an alien cannot hold lands the crown may enter, upon office found. [OFFICE FOUND.]

Offices are forfeited by the neglect or misbehaviour of the holders; and the right to the next presentation to ecclesiastical benefices is forfeited by simony and by lapse. Simony is the corrupt presentation of any one to an ecclesiastical benefice for money, gift, or reward. Lapse is where the patron neglects to present to a benefice within six months after it has become vacant, in which case the right to present accrues to the ordinary; by neglect of the ordinary for the same space of time, to the metropolitan; and by the like neglect of the metropolitan, to the crown. [BENEFICE.]

FORGE; FORGING MACHINE. Many improvements have been introduced in recent years in the apparatus for forging or hammering heated iron. We do not advert here to the marvellous powers of Nasmyth's steam hammer [HAMMER], but to contrivances of a smaller and more generally applicable kind. As is well known, a common smith's forge consists chiefly of a hearth on which the burning fuel is placed, bellows for exciting the intensity of the heat, anvils on which to rest the heated metal while being forged, and hammers and swages to bring the metal into form. An anchorsmith's forge is somewhat similar, but on a larger scale. The recently-invented forges, however, are all intended to effect something more than can be accomplished by the ordinary forge, either in quantity or in kind. We will adduce a few instances.

Richards's forging machine accomplishes all the operations of heating, holding, carrying forward, turning, and hammering the piece of heated metal which is under process. The face of the hammer has a peculiar curved movement, to draw the piece of metal forward; and the swages or shaping dies, carried on the lower side of the hammer, have such forms and positions that the heated metal, placed between them and the anvil, is made to assume a shape successively nearer and nearer to that which is desired.

Chaplin's forge is compact and portable, and gives out an intense heat. An upright iron frame contains the blowing apparatus. A sheet-iron tray is mounted on wheels: and an upright front is attached to the tray by a single bolt. The fuel is contained in a long concave pan of cast-iron, bolted to the frame, the bolts acting as hinges for folding up; and the opposite end of the pan is supported by two standards. An adjustable dead-plate is fitted to the inner front of the frame, to prevent the injurious action of the heat on the blowing-machine. A portable hinged hood is so fitted as to reflect the heat downwards, and carry off the smoke. A cold-water trough is hooked upon the end of the fire-pan. The blowing apparatus consists of small fans placed near the bottom of the frame; it is driven by a band from a pulley on the spindle of a winch-handle: or, in another arrangement, a treadle is used instead of a winch, thereby leaving the hand at liberty. This ingenious arrangement of parts would render the forge available as a shot-heater, or for melting small quantities of iron or brass; for the latter purpose, the fire-pan is superseded by a cupola lined with fire-clay. So intense is the heat produced in this forge, that a bar of iron an inch and a half in diameter can be brought to a welding temperature in four minutes.

Hattersley's forging machine comprises such an arrangement of swages, dies, or hammers, as effects great saving of time, and enables the forging to be finished in one heat. There is a rapid mode of transferring the bars of heated iron from one pair of swages to another.

Ryder's machine consists of a series of hammers, or vertical stampers, so varied in shape as gradually to forge the heated metal into the desired form. The patent for this machine expired in 1855, and application was made for a renewal, on the ground that the invention had only become profitable when the patent was nearly out; but this application was refused.

The last which we shall notice is Campbell's steam-forge, which combines both a blowing and a striking apparatus. It is worked by a small steam-engine, which obtains its steam partly by the action of the forge fire. There is a small horizontal steam-cylinder attached to the frame which carries the forge-hearth, and connected with the frame is a system of shafts, speed-wheels, pinions, &c., to move the piece of metal which is to be acted on, and also the hammer. There is a blowing-fan making sixteen hundred revolutions in a minute. The boiler for the steam-engine is over the hearth. The forge-anvil is placed by itself on the floor, at the other end of the machine. The hammers are attached to levers on a horizontal shaft in the hearth-frame, and are set in motion by the steam cylinder, through the medium of a long sliding rod which strikes the tail of the lever or levers. Hand-gear is provided for working the hammers if steam-power should not be available.

FORGERY is the false making, counterfeiting, altering, or uttering any instrument or writing with a fraudulent intent, whereby another may be defrauded. The offence is complete by the making the forged instrument with a fraudulent intent though it be not published or uttered, and the publishing or uttering of the instrument, knowing it to be forged, is punished in the same manner as the making or counterfeiting.

It is by no means necessary to bring the offence within the legal meaning of the term forgery, that the name of any person should be counterfeited, though this is the most common mode in which the crime is committed; thus a man is guilty of forgery who antedates a deed for the purpose of defrauding other parties, though he signs his own name to the instrument; and the offence is equally complete, if a man being instructed to make the will of another, inserts provisions of his own authority. In truth the offence consists in the fraud and deceit.

At common law the crime of forgery was only a misdemeanour, but as the commerce of the country increased and paper credit became proportionally extended, many severe laws were enacted, which in most cases made the offence a capital felony.

The extreme severity of these laws tended to defeat their object, and parties very frequently chose rather quietly to sustain the loss inflicted upon them by the commission of the offence, than by a prosecution to subject the offender to the loss of life. This feeling, and the diffusion of the truth, that the object of all laws is to prevent crime and not merely to punish, has caused successive mitigations in the laws relating to forgery, and now by various statutes, particularly the 11 Geo. IV., and 1 Will. IV. c. 66; 2 & 3 Will. IV. c. 59, and 1 Vict. c. 84, the punishment of death is abolished in cases of forgery, and a punishment varying between transportation for life (now penal servitude) and imprisonment for one year is substituted.

(1 Hawk, P. C.: Russell *on Crime;* Deacon's *Criminal Law.*)

FORK (Anglo-Saxon *forc;* the same as the Latin *furca*), an instrument divided at the end into two or more prongs for various uses, especially for the table. Addison speaks of a thunderbolt with three forks. It is sometimes used for an arrow, and in old English for a gallows or gibbet. Butler, in his 'Remains' (ii. 195), says, "They had run through all punishments, and just 'scaped the *fork*." The furca was an instrument of punishment among the Romans. Criminals convicted of serious crimes were fastened to it and then scourged to death; but it was also used for slighter punishments, and for some offences slaves were condemned always to carry it about with them: hence the use of the word "furcifer" as a term of reproach.

The agricultural or dung-fork, and a large fork for the flesh-pot, were the only implements of this name apparently in use among our early ancestors. The first mention of table or eating forks is probably found in the 'Chronicon Placentinum' of John de Mussis ('Muratori,' vol. xvi., p. 584), a writer of the early part of the 15th century, who, when speaking of the luxuries of the people of Piacenza recently introduced, says, "they use cups, and spoons, and *little forks* of silver" ("et utuntur taciis, cugiariis, et *forcellis* argenti"). But the fork must have been in use in some parts of Italy some centuries earlier, if Alberti ('Urbis Venetæ Descriptio,' Venice, 1626, p. 221) be correct in asserting that it was regarded as a mark of pride in the wife of the Doge Domenico Silvio, who flourished towards the close of the 11th century, that she would not use her fingers, but employed a fork in eating ("cibum non digitis sed *furcillis* aureis caperet"). Coryate, in his 'Crudities' (edit. 1611, p. 90), announces himself as the person who introduced this Italian fashion into England. He says, "Here I will mention a thing that might have been spoken of before, in discourse of the first Italian town. I observed a custom in all those Italian cities and towns through the which I passed, that is not used in any other country that I saw in my travels; neither do I think that any other nation of Christendom doth use it, but only Italy. The Italian, and also most strangers that are commorant in Italy, do always at their meals use a little fork when they cut their meat. For while with their knife, which they hold in one hand, they cut the meat out of the dish, they fasten their fork, which they hold in their other hand, upon the same dish, so that whatsoever he be that, sitting in the company of any others at meal, should unadvisedly touch the dish of meat with his fingers from which all at the table do cut, he will give occasion of offence unto the company, as having transgressed the laws of good manners, insomuch that for his error he shall be at the least browbeaten, if not reprehended in words. This form of feeding, I understand, is generally used in all places of Italy, their forks being, for the most part, made of iron or steel, and some of silver, but those are used only by gentlemen. The reason of this their curiosity is, because the Italian cannot by any means endure to have his dish touched with fingers, seeing all men's fingers are not alike clean. Hereupon I myself thought good to imitate the Italian fashion by this forked cutting of meat, not only while I was in Italy, but also in Germany, and oftentimes in England since I came home: being once quipped for that frequent using of my fork, by a certain learned gentleman, a familiar friend of mine, one M. Laurence Whitaker, who, in his merry humour, doubted not to call me at table *furcifer*, only for using a fork at feeding, but for no other cause." Coryate's testimony is confirmed by Fynes Morison, in his 'Itinerary' (P. i., p. 208, fol., 1617), who, speaking of his bargain with the patron of the vessel which conveyed him from Venice to Constantinople, says, "he gave us good diet, serving each man with his knife, a spoon, and a fork." Ben Jonson, in 'The Divell is an Asse' (act v. sc. 4), makes Mere-Craft speak of his "pains at court" to get a patent for his "project" for "the laudable use of forks, brought into custom here as they are in Italy, to the sparing of napkins;" and that they are to be "of gold and silver for the better personages, and of steel for the common sort." See also his 'Volpone,' act. iv. sc. 1.

Even when Heylin published his 'Cosmography,' in 1652, forks for the table were still a novelty: see his third book, where, having spoken of the ivory sticks used by the Chinese, he adds, "the use of silver forks with us by some of our spruce gallants taken up of late, came from hence into Italy, and from thence into England."

FORM. Everything that exists may collectively be termed the "something," in opposition to the "nothing." This "something" divides itself into four great divisions, namely, things, ideas, forms, and appearances. Form is the manner and mode in which a thing is presented to our conceptions. Things are of two descriptions: immaterial, as faculties and intellect; and material, as matter and bodies. The forms of the immaterial things are called categories; the forms of the material we may call figures; the form of appearances retains the name of form; and ideas are formless. The categories, according to the opinion of the writer (founded upon those of Aristotle, Kant, and many others), are the following:—1. Categories of position,—to be, not to be, and to become; 2. Categories of quality,—substance, accident, and mode; 3. Categories of relation,—cause, effect, and action and reaction; 4. Categories of quantity,—universality, multiplicity, and unity. The logical categories are possibility, actuality, and necessity. [CATEGORY.] The figures, on account of their variety, do not admit of being classified, yet we may divide them according to the senses, into shapes, colours, sounds, smells, and tastes, and into the different modes of feeling.

Form is distinguished from the real nature of things, and, considered in this point of view, the idea of form is practically used in common speech and in science. Thus we speak of a form of law, a form of government, a beautiful form, a logical form, &c. Whoever esteems the form of anything more highly than the thing itself, or through narrow-mindedness confounds the one with the other, is a formalist, as many learned men and official persons are.

FORMÂ PAUPERIS. By stat. 11 Hen. VII. every poor person shall have original writs or subpœnas, without paying for writing or sealing the same; and the judges of all courts of record, where such suit shall be carried on, are authorised to assign clerks to write, and counsel and attorney to act for such person, without taking any reward. It is discretionary with the court to grant this indulgence, but it is rarely refused upon petition, supported by affidavit that the petitioner is not worth 5*l.* in the world after paying his just debts, exclusive of his wearing apparel, and the right to the matter in controversy, and by a certificate by a barrister that he has good cause of action or suit. The Court of Chancery has from an early period permitted parties to sue and defend as paupers upon the same conditions as the courts of law, though in that court, it seems, if the party be in possession of the subject matter in dispute, and that should be worth more than 5*l.*, he cannot except it in his affidavit, and therefore will not be regarded as a pauper. The privilege may be granted either at the commencement of the suit, or at any period of its progress, but if granted during the pendency of the suit, it has no retrospective effect, and the party is not relieved from the costs previously incurred.

A person allowed to sue *in formâ pauperis* pays neither for stamps, nor fees to the officers of the court, but if he obtains a verdict with damages above 5*l.*, the officers take the fees. In case of improper or vexatious conduct on the part of the pauper, the courts will deprive him of the privilege, which is called dispaupering him; but it seems that in such cases a pauper plaintiff is never ordered to pay costs to the defendant, though, according to Blackstone, a pauper, if non-suited in his action, formerly had his election either to be whipped or pay costs.

FORMEDON (a compound of the two Latin words *formam doni*), one of the many writs in use under the old law for commencing a real action, before the more convenient mode of trying titles to land by ejectment was established. [EJECTMENT.] It was the peculiar remedy of a tenant in tail, who claimed *per formam doni*, and the highest he could have, and was therefore called tenant in tail's writ of right. The writ of right was granted to such only as claimed the fee simple, for which reason the statute *De Donis* (Westm. 2, 13 Ed. I.) gave this writ to tenants in tail. Together with all the others used for the commencement of real actions, it was abolished by stat. 3 & 4 Will. IV c. 27, s. 36.

FORMEN. [Methyl, *Hydride of.*]

FORMIC ACID. [Formyl.]

FORMIC ETHER. [Formyl.]

FORMULÆ, CHEMICAL. [Chemical Formulæ.]

FORMYL. This name was originally applied to a hypothetical radical (C_2H) supposed to be contained in formic acid, chloroform, and other bodies, but it is now exclusively used to denote the oxygenous radical of formic acid $\left(\begin{matrix}C_2HO_2\\C_2HO_2\end{matrix}\right\}\Big)$. This radical is unknown in a separate condition, but in combination with oxygen and water it constitutes—

Formic acid, C_2HO_3HO, which originally obtained its name from having been found present in the red ant (*Formica rufa*). Hence also the name of the radical formyl. This acid may be procured from methylic alcohol, $C_2H_3O + HO$, by the loss of two equivalents of hydrogen, and the addition of two of oxygen. It may also be procured by mixing starch or sugar with peroxide of manganese, water, and sulphuric acid, and distilling. It is formed also under a great variety of other circumstances. It unites with lead, forming a formiate of lead, and from this, formiate of soda may be procured by the addition of carbonate of soda. It unites freely with most of the metallic oxides, and many of the salts when heated in closed vessels give off carbonic acid and carbonic oxide, leaving the pure metal. It unites also with ammonia, the salt thus formed containing the elements of hydrocyanic acid and water.

It is the first or lowest member of the important series of Fatty Acids. Formyl also enters into the composition of the following compounds:—

Formic ether $\left(\begin{matrix}C_2HO_2\\C_4H_5\end{matrix}\right\}O_2\Big)$ may be obtained by distilling a mixture of formic acid and alcohol; but it is much better procured by distilling a mixture of 10 parts of concentrated sulphuric acid, 7 of formiate of soda, and 6 of alcohol. The distilled product should be mixed with water to separate the alcohol which it contains, then agitated with magnesia to saturate any excess of acid, and lastly, freed from water by distillation with chloride of calcium. This is Döbereiner's process.

Formic ether is a colourless liquid, of a strong odour, resembling that of peach kernels; its taste is peculiar. Its sp. gr. is 0·915 at 65°, and it boils at 132° Fahr. It mixes with alcohol in all proportions; but water takes up only ⅑th of its weight; and after some time the solution is found to be converted into a mixture of alcohol and weak formic acid: this ether burns in the air with a blue flame, the edges and point of which are of a bright yellow.

Formobenzöilic acid ($C_{32}H_{16}O_{12}$). A composite acid, which stands in the same relation to the benzoic series as lactic acid does to the acetic series.

Formanilide, Phenyl-formiamide ($C_{14}H_7NO_2$). One of the products of the action of heat upon oxalate of aniline. [Anilides.]

FORMYLIA. An organic base so-named by Clöez, but which has since been proved by Hofmann to be *ethylene-diamine* ($N_2C_4H''_4H_4$). It is formed by the action of bi-bromide of ethylene upon ammonia.

FORNAX (Constellation), the Chemist's Furnace, one of the southern constellations of Lacaille. It is situated immediately below Cetus. It does not contain any stars of conspicuous brightness.

FORT is the term applied to any enclosed field work, or small permanent work. It is however often very loosely applied.

FORTE (Italian *strong*, *loud*), a musical term, directing the performer to sing or play loudly, with strength.

Fortissimo is the superlative of *Forte*.

FORTRESS, a fortified city or town, the works of which are such as to require an attack in form, or are capable of resisting an attack de vive force.

FORTIFICATION is the art of constructing works for the protection of a town or military position; the object being to enable a lesser force to be a match for a greater from the advantages of its position. Or, as in the case of offensive fortification, such as siege works, to increase the power of the assailants. Fortification has, therefore, been divided into two parts, *permanent* and *field*, the former comprising such works as are intended to last for many years, and the latter such as are hastily executed for the defence of a position of an army in the field, or the attack of a fortress.

The principles which regulate the general plan of the works constituting the fortifications of a town or great military post, have at all times been nearly the same. Among the ancients, with scarcely any exception, the polygonal wall surrounding a place was provided with towers projecting from it at intervals towards the front; and a barbacan, or outwork, consisting of two or more towers, connected by walls like those of the fortress itself, was generally constructed on the exterior side of the ditch and opposite a gate of the town, in order to protect that entrance and the bridge leading to it. The towers and walls about an ancient town correspond to the bastions and curtains forming the enceinte of a modern fortress, and the barbacan may be considered as the counterpart of its ravelin, or principal outwork.

The necessity which the nations of Europe were under of remodelling their fortified towns in consequence of the change produced in the art of war by the invention of gunpowder, gave occasions for the engineers of Italy, France, and the Netherlands to emulate each other in devising the most advantageous methods of disposing the works for the purposes of defence with relation to the arms then newly introduced; and the result of their labours was the construction of numerous strong fortresses on the frontiers of those countries. In these the bastion system, as it is called, was invariably adopted [Bastion]; and it is remarkable that, of the very numerous projects which have been offered to the world for fortifying places, so few should have been till latterly of a different kind. The variations however which occurred in the details of the plans gave rise to the denominations of the Italian, the French, the Spanish, and the Dutch methods, in speaking of the works proposed or executed at the end of the 16th and the beginning of the 17th centuries; but it must be observed that those variations consisted chiefly in the magnitude of the angle which the two faces of a bastion made with each other, and in the extent of what was called the second flank; that is, the portion of the curtain then generally left between the flank of a bastion and the place where the produced face of the collateral bastion intersected the curtain.

The first bastioned fortresses of France appear to have been very inferior to those which were executed in the Netherlands by the Italian engineers; and there still exist some remains of these last in which the bastions are sufficiently capacious, and at distances from each other within the effective range of musket-shot. The others, on the contrary, were characterised by small bastions, scarcely capable of receiving artillery, and placed so far asunder as to defend each other very imperfectly. But after the termination of the civil wars which desolated the country, the attention of the French government was directed to the state of the military posts; and Errard de Bar le Duc, a member of the corps of engineers then instituted, was appointed to superintend the reparation of the old, and the construction of the new fortifications. The citadel of Amiens was built according to the plan proposed by this officer, who, in 1594, published a treatise on fortification, in which some effort is made to determine the principles which should regulate the forms and dimensions of the works; his method, however, is only a faulty modification of the Italian.

In the method proposed by Errard the bastions are much larger than those of the earlier time, the length of their faces being, as at present, about one-third of the distance between the salient angles of two collateral bastions; an orillon occupied nearly two-thirds of the length of each flank, which was very short, and formed an angle of about 80° with the curtain. This direction appears to have been given to the flanks in order that the guns behind their parapets might be as much as possible concealed from the view of the enemy in his counter-battery; but it is evident that the defenders of the opposite flanks, laying their muskets perpendicularly to the lengths of the parapets, according to the general practice, would almost inevitably, especially in the dark, fire upon each other, or upon those who were stationed on the curtain.

De Ville, who composed a treatise on fortification in 1629, made several improvements on the method proposed by Errard, the principal of which were an augmentation of the length of the flanks and a perpendicular direction of the latter with respect to the curtain: by these changes a better defence was obtained from the flanks, and the evil above mentioned was diminished. But a still greater amelioration was made by Count Pagan, who, in 1645, proposed to make each flank [see the half-front of Fortification between F and G, fig. 1, Bastion] perpendicular to the produced face of the collateral bastion; the reciprocal defence which the works should afford each other is thus complete, and the men are not in danger of being fired on by each other. Pagan retains the orillons at the shoulders of the bastions, and he gives to the latter double or triple flanks; but the construction of these, and of many other works supposed to be modern improvements, such as the demi-revetment, are to be found in Castriotto's work, published in Venice in 1564: they have, however, on account of their numerous inconveniences, ever since been discontinued.

During the reign of Louis XIV. a general reparation or reconstruction of its fortresses was ordered by the French government; and the talents of Vauban, which were exercised in devising and carrying into execution, the strengthening and improving 300 places and the building of 33 new ones, together with the merit displayed in the conduct of fifty-three sieges, have given that engineer so much celebrity. Besides the changes made in the disposition of the parts of the enceinte, the outworks were entirely remodelled; and instead of assigning for the delineation of the plan, numerous arbitrary rules which varied with the nature of the polygon, Vauban adopted the length of the side of the polygon as a base, and took certain aliquot parts of this line for the dimensions of the several divisions of the rampart; thus reducing the construction to a few simple precepts which were applicable to places of all magnitudes. These precepts being founded on the uses of the works may be justly considered as constituting a system of fortification, though many of his works are found in older writers; and from that time to the present scarcely any deviations have been made from them in the construction of great fortresses. A brief outline of the system will therefore be here given. [See the half-front of fortification between G and E, *fig.* 1, Bastion.]

The length of each side, as F E, of a regular polygon supposed to surround the town or position, is made from 320 to 400 yards, say about 380 yards, in order that all the parts of the rampart on each front of the enceinte might be within the range of the arms employed in the defence, but more especially that the faces of the bastions should be within range of the flanks. This for the old smooth-bored musket would have required a range of 180 to 200 yards, but this being impracticable from the relief required in the bastion, and from its further rendering the bastion too small, the length is determined by the range of rifles, wall pieces, and grape shot, which is about 300 yards. Now these being supposed to be placed on the flanks, as at *e* or *f*, might be employed to oppose the formation of the counter-battery at H, or at the corresponding point on the left of F; therefore, if we assume the length of the line from *e* to H to be 300 yards, and deduct from it the estimated breadth of the main ditch and covered-way (40 yards), we have 260 yards for the length of *e* E or *f* F, which is called the line of defence. This is also the distance of E or F from the shoulder of the collateral bastion; and if we add to it the length of the face of the bastion, which is 103 yards, or 2·7ths of E F, in order that, in the inferior polygons, the bastion may have sufficient capacity, we obtain about 380 yards for the distance between the salient points F and E of the two bastions; and it may be observed, that a few yards more or less in the dimensions need not be regarded.

The directions of the faces of the bastions on each front coincide with lines drawn from the angles E and F of the polygon, through the extremity of a perpendicular let fall from the middle of the line E F and made equal to one-sixth of that line; and each flank is the chord of an arc, described either from the opposite angle E or F of the polygon, or from the nearest shoulder of the collateral bastion, as a centre. By this construction the flank is rather greater in length than the enemy's counter-battery, which is necessarily limited by the angle of the glacis and the prolonged face of the nearest bastion; and it is nearly perpendicular to the direction of that face: the reason why it is not made exactly so is, that a man on the flank, placing his musket perpendicular to the line of parapet, will thus be able to fire into and defend a breach which may be made in the face of the collateral bastion. The curtain is determined by a line joining the interior extremities, near *e* and *f* of the flanks; and, with the height which Vauban assigned to the rampart of the enceinte, this length will permit the fire of musketry from each flank to defend the opposite half of the ditch between the flanks. The line which on the plan indicates the directions of the faces, flanks, &c., of the works, is called the magistral line; it forms the exterior side of the ramparts in *fig.* 1 [BASTION], and coincides with the cordon, or projection, at the top of the revetment N, *fig.* 2.

The dimensions of the ditch are determined by the necessity of obtaining from it the earth for the formation of the ramparts and parapets, the depth being fixed by giving the escarp the least height which is considered quite secure from escalade. This for the main works should be about 32 feet, which gives a breadth of ditch at the flanked angles of the bastion of 38 yards. The counterscarp wall is rounded opposite the flanked angles at E or F, and is directed from thence towards the shoulder of the collateral bastion.

The improvements made by Vauban in the ravelin are described under RAVELIN: Q represents one-half of that work; and it will be merely necessary here to say, that its plan is determined by using the angular points near *e* and *f*, formed by the magistral lines of the flanks and curtain, as centres, and with radii equal to the distances from thence to points taken on the faces of the collateral bastions, at 10 yards from their shoulders, describing arcs; the intersection of these arcs determines the salient angle of the ravelin; the magistral lines of its faces tend from that intersection to the points just mentioned, and terminate on the counterscarp of the main ditch.

The traverses in the covered way were proposed by Vauban, in order to diminish the effect of the ricochet fire of the besiegers, which Vauban was the first to employ in the attack, in which he was even more famous than in the defence, being the first to give it that decided superiority which it has ever since maintained, and one of the principal means of which was the ricochet fire. He was the first engineer who formed the spacious places of arms, as they are called, at L, in the re-entering parts of the covered-way, in order to obtain room for assembling troops, and to afford a good crossing fire of musketry from their faces for the defence of the glacis in front of the bastions and ravelins.

An attention to the reliefs of the several ramparts of a fortress is no less necessary than to the plans; for, as it would be advantageous, when the approaches of the besiegers are near the foot of the glacis, that a fire of artillery should be made from the ramparts of the enceinte or ravelin, and of musketry from the covered-way at the same time, the reliefs of those ramparts should be determined by imagining a line to be drawn from the foot of the glacis through a point 3 or 4 feet vertically above the crest of the latter, that is about 11 feet above the ground, and to be produced through the parapet of the said enceinte or ravelin; then, if the soles of the embrasures, which are necessarily 4½ feet below the crest of the parapet, be made to coincide with such imaginary line, the fire of artillery from them may be directed to the enemy's trenches without incommoding the defenders of the covered-way. The crest of the enceinte thus determined will be about 18 feet above the ground, and that of the ravelin about 3 feet less.

The tenaille, P, *fig.* 1 [BASTION], will be described under that word; but it may be mentioned here that the relief of this work is determined by the consideration that, while it should be high enough to mask the postern in the curtain behind it, the men stationed on it to defend the ditch should be below the lines of fire from the flank of one bastion, when directed to the foot of a breach supposed to be made near the shoulder of that which is collateral to it, in order that they may not be injured by that fire.

As Vauban had occasionally to adapt works constructed according to the principles above mentioned, to the old fortifications which then existed, the particular method employed in disposing them acquired the denomination of his second system; and when, subsequently, he fortified Neu Brisach, some few modifications which he was led to make gave rise to a new distinction, the works of that place being considered as forming a third system. In both these systems the bastions V, *fig.* 3 [BASTION], are separated by a ditch from the enceinte; and this circumstance is so far advantageous, that the place would not be compelled to surrender immediately upon those works being taken by the besiegers. The enceinte consists of a long curtain, either quite straight or broken by two short flanks; and at the angles of the polygon are small bastion-towers of masonry (T, *fig.* 3), in whose flanks are formed casemates to contain artillery for the defence of its ditch. This great engineer died in 1707, at the age of 74 years; and, from his time, the French fortification has been to a great extent that of all Europe.

It would be improper in this place to omit the name of Minno, Baron of Coehorn, who was born in the year 1641, the year preceding the birth of Vauban, and who in the service of the United Provinces acquired a reputation scarcely inferior to that of his great rival. In the year 1692 they were directly opposed to one another, Coehorn defending Namur against Vauban, who conducted the attack. His system, or systems, as he in his treatise describes three, are essentially adapted to aquatic sites, such as those of Holland, and he applied them, with the modifications required by the ground, to Nimeguen, Breda, Manheim, Namur, and Bergen-op-Zoom. Tilbury Fort is also on his system. The outline of the plan differs but little from that of his rival's great system, but the shoulders of the bastions are strengthened by large towers, or orillons, containing casemates. In the interior of each bastion is another, on a higher level, and on the exterior is a counterguard, consisting of two faces, parallel to those of the bastion. A large ravelin, inclosing a redoubt on a higher level, is placed before the curtain, and the whole is surrounded by a broad covered-way, whose places of arms are retrenched by brick redoubts. The plane of site of the works is assumed to be 4 feet above the level of the water, which allows the system to combine the advantages of wet and dry ditches. When the wet ditches are employed the expense of the revetment is saved, and the dry ditches which separate the unrevetted portions from the principal works afford the garrison a great advantage in resisting the besieger while defiling from his bridge across the wet ditch to attack the inner works, which have a sufficient revetment to resist an assault without ladders, but are still low enough to be protected from distant fire. The terrepleins, as well of the bastions and ravelins as of the covered-way, are sunk below the natural surface of the ground, so that it would be impossible, in the marshy soil on which the fortifications are supposed to be constructed, for an enemy to dig trenches there in order to form covered approaches. The terrepleins of the principal works are also well defended by fire from the covered galleries which cross them, or which are formed within the masses of the ramparts.

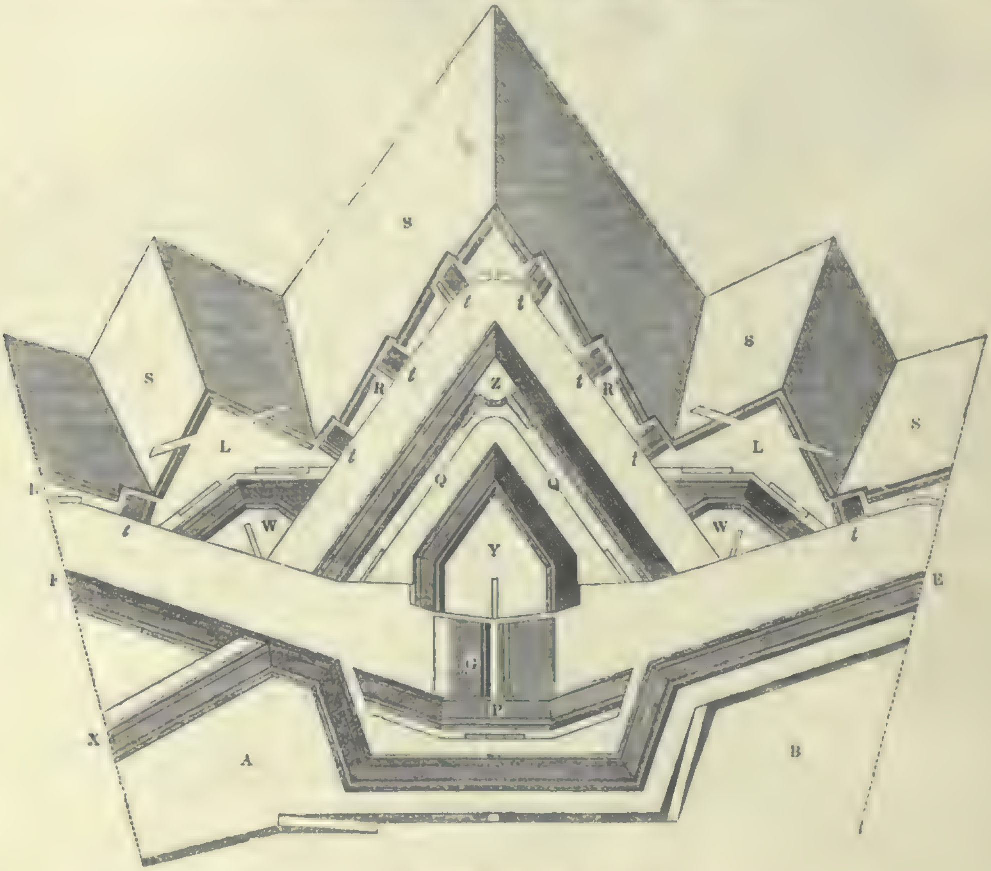
It should be observed that the salient points, E, F, &c., of the bastions and ravelins in Vauban's system being nearly equally distant from the centre of the place, the trench executed by the besiegers to connect the glacis before the former works will also connect that which is before the latter; and that, in consequence of this construction, breaches may be formed, and assaults made, at one time, in the enceinte and outworks. With the view, therefore, of preserving the former untouched till some time after the ravelins may have been taken, the French engineer Cormontaingne proposed, about 30 years after the death of Vauban, to advance the salient points of the ravelins as much as possible, by increasing the length of the faces to the utmost limit which a regard to the due magnitude of the flanked angle will admit. Thus the magistral line of his ravelin is determined by directing its faces on the faces of the collateral bastions, at 22 yards from the shoulders; and its salient or flanked angle by the intersection of the perpendicular produced of an arc described from one of these points as a centre, and the shoulder of the opposite bastion as a radius. By this construction it would become impossible for an enemy to crown the glacis of a bastion till he had got possession of the two collateral ravelins, on account of the fire which, from these, might be made upon his approaches between them; and the fall of the place would be delayed by the time spent in conducting the approaches from the ravelins to the intermediate bastions.

In order that this benefit might be obtained in the highest degree, Cormontaingne suggested the propriety of fortifying places on polygons of the superior kind, and even, when possible, of constructing two or more fronts of fortification on one straight line; this practice would have the additional advantage of rendering the flanked angles of the bastions very obtuse, by which, not only would the increased capacity of those works permit stronger retrenchments to be formed in them, but the faces being produced outwards, would tend to points on the faces of the ravelins, and thus would be completely secured from the enfilading fires of the besiegers.

Besides the above general modifications, Cormontaingne made several improvements in the details of the works. He made the flanks exactly perpendicular to the prolonged faces of the collateral bastions, for the sake of a more complete flanking defence. He made the terrepleins of the ravelins merely wide enough to contain the artillery of the defenders; in order to increase the capacity of the redoubt in the ravelin, and to deprive the enemy of the space necessary for a battery on the ravelin, by which he might breach that redoubt. He also gave large casemated flanks to the latter work, in order that a powerful fire might be directed from them against the enemy, if he should attempt to mount the breach in the face of either bastion before he had got possession of the redoubts as well as of the ravelins themselves. A further improvement was made by this engineer in adding to each of the re-entering places of arms a spacious redoubt, which would render the defence of that place more obstinate, and cover the passage between the tenaille and the flank of the bastion. The following are the commands of the principal works above the country.

Salient of bastion	26½	feet decreasing 1 foot to flank of do.
Salient of redoubt of ravelin . .	24	" "
Salient of ravelin	22	" extremity of face.
Redoubt in Re-entering place of arms	14	
Tenaille	8	
Covered-way	9	

Plan of a Front of Fortification according to the Method of Cormontaingne.



80 yards to an inch.

A. Solid Bastion; B, Hollow ditto; X, Retrenchment; P, Tenaille; G, Caponnière; Q Q, Ravelin; Y, Redoubt in ditto; L L, Re-entering places of Arms; W W, Redoubts in ditto; R R, Covered-way; t t, Traverses; S S, Glacis; E, Barbette battery.

Cormontaingne's system, to which the name of French modern system was for some time applied, has at various times been modified in many of its details, especially by the French engineers at their schools of application (formerly at Mezieres, and now at Metz), and at the present time the term of Modern System is applied to one which may be considered as the most perfect Bastioned trace, and which is taught in the French engineer schools as the normal bastion trace. The proportions given by Cormontaingne to the enceinte are retained with the exception that the flank is increased by directing the escarp of the faces of the bastion to the angle of the flank of the magistral line instead of to the interior crest. The saliency of the ravelin is however still farther increased, and it is in this that the principal modification of the modern system lies, by directing its faces on the faces of the bastion points 36 yards from the shoulders, and giving the salient or flanked angle the greatest saliency possible, allowing it in fact only an opening of 60°, which is the least admissible. The ravelin being thus enlarged allows of a larger redoubt, though the terreplein of the ravelin, which Cormontaingne only considered a species of counterguard, is also increased. A permanent coupure is made across each face of the ravelin at the point where a perpendicular from the extremity of the magistral line of the nearest face of the redoubt of the covered way cuts it in order that the besieger may not by sapping along the face of the ravelin, and thus be able to see into and drive the defenders out of the redoubt. The greater saliency of the ravelin allows of four traverses in the covered way instead of the three, according to Cormontaingne's system.

The modern system however has some important defects, among which the principal are that the ravelin and its covered way present long lines easily enfiladed, and the faces of the bastion may be breached by the besieger firing down the ditch of the ravelin from his breaching battery on the crest of the glacis at its salient, even more easily than in Vauban's first system. The flanks of the bastion also being brought closer together, increase the undefended portion in front of the curtain and tenaille. To remedy these defects, Colonel Dufour has proposed certain modifications. Taking the outline of the enceinte and of the ravelin, the same as those of the modern system, he raises a large mound at the salient of the latter by laying off 45 yards along each face, and raising it 44 feet above the plane of site or level of the country. This by its elevation entirely screens the faces of the ravelin from enfilade fire. Again the inner face and ditch of the redoubt of the re-entering place of arms, instead of terminating on the counterscarp of the ditch of the ravelin, is continued across the ditch to the counterscarp of the ditch of the redoubt of the ravelin, perpendicular to its face at the shoulder angle, cutting off therefore the face of the ravelin by making a coupure in it and preventing the besieger breaching the bastion down its ditch. The flanks of the redoubt of the ravelin are simply crenelled walls, in order not to give the besiegers any cover from which to drive the defenders from the redoubt of the covered way and the coupure of the ravelin, which are intended to be held till the last.

Soon after the commencement of the revolution, Bousmard, a French officer, who had entered the service of the king of Prussia, proposed to curve the faces of the bastions on the plan, in order to diminish or prevent the effect of the ricochet, and to build casemates in the flanks of the tenailles for the purpose of more effectually defending the main ditch. His traverses in the covered way are like little redans, each being a little retrenchment having a separate communication with the main ditch. But his principal improvement consisted in extending the covered way and glacis along the whole of the enceinte, and in placing the ravelin with its proper covered way and glacis on the exterior; in consequence of which disposition it would become impossible for the besiegers to breach the bastion by firing along the ditch of the ravelin, while the latter would possess all the advantages attending the greatest possible saliency. The ideas of Bousmard respecting the disposition of the ravelin were adopted by General Chasseloup de Labat, in the works which he executed, by order of Napoleon I., to strengthen the fortifications of Alessandria; and the same engineer constructed a strong polygonal redoubt of earth in each of the places of arms before the flanked angles of the bastions and ravelins, in order to increase the quantity of crossing and reverse fires in front of the works.

The last modification of the bastion system which it will be necessary to mention, is that proposed by Choumara, who, partly to diminish the pressure of the parapets on the escarp revetment, and to render the formation of a practicable breach more difficult, and partly to procure a close fire of musketry into the covered-way, suggests that a terreplein, like the old chemin des rondes, but with a slender breastwork to protect the defenders, should be left on the exterior of the parapets. The same engineer recommends that the flanks of the bastions should be lengthened by continuing them within the line of the curtain, and that they should have a greater relief than the latter, in order that a fire of artillery might be directed over it against the works of the enemy: he proposes also that a glacis of earth should be raised in the main ditch, high enough to mask the foot of the escarp revetment, and prevent it from being battered by a fire of artillery on the crest of the covered way.

As early as 1640, Dillichs, in a work published at Frankfurt, proposed a method of fortifying places, which consists in surrounding them by lines of rampart forming with each other a series of angles alternately salient and re-entering, being in fact a Tenaille system; and, subsequently to the time of Vauban, a few other projects of a like nature have been suggested. The most remarkable of these is that which was published in 1776 by the French General Montalembert, who entitles his method 'Fortification Perpendiculaire.' Its outline on the plan is a series of the sides of equilateral triangles formed on those of a dodecagon inclosing the place; the re-entering angles being consequently right angles, and, as the general has developed some useful ideas concerning the interior defence of a place, though no existing fortification affords an example of the method, a short description of it may with propriety be given.

Three parallel ramparts of earth, of the form above indicated, and separated from one another by wet ditches, surround the place: the berme at the foot of the first and third is protected by a simple wall, and that at the foot of the middle rampart is covered by a loop-holed gallery on its whole length. Beyond the outer ditch is the covered-way, whose re-entering angles are fortified by strong redoubts. In the re-entering angles of the two interior ramparts are formed casemated batteries, the fires from which would sweep the surface of the ditches in front, in the directions of their lengths; and, within the enceinte of the place, a circular redoubt, or tower, of brick-work, carrying several tiers of guns, is intended to defend the interior rampart, if, at length, it should be forced. The merit of this system is supposed to consist chiefly in the powerful fire which the casemates would afford, as from their situation, they would scarcely be injured by the enemy; in the difficulty which the latter would experience in getting over the detached walls; and in the great force which the defenders, by means of the spacious communications, might bring up to oppose the assailants.

During the existence of the first French empire, the celebrated Carnot proposed to restore the balance between the attack and defence of fortresses, which the inventions of Vauban had made to preponderate greatly in favour of the former, by means of powerful sorties from the place and an abundant discharge of stones and balls from mortars fired at considerable angles of elevation; thus annoying the besiegers in their trenches, and either putting great numbers of their men hors de combat, or compelling them to recur to the slow process of blinding their approaches. Adopting, in his method of fortifying places, the proportions of Cormontaingne for the plan of his bastions, but making the whole length of his front of fortification equal to 480 yards, he detached the bastions from the enceinte, which he made to consist of a simple polygonal rampart of earth. In rear of the tenaille between the bastions he placed a fausse-braye, whose exterior side was to be protected by a casemated tower at each extremity; and, behind the gorge of each bastion, he formed a row of casemate vaults, in which the mortars were to be placed for throwing stones, &c. into that work when gained by the enemy. Adopting also the ideas of Montalembert respecting detached walls, he proposed to surround the enceinte by one, which was to be loop-holed in order that a fire of musketry might be made from it, and to construct a similar wall before the faces and flanks of the bastions. The bastions were to be covered by narrow counterguards; a cavalier, or lofty redoubt, in front of the tenaille, was to defend the collateral faces of both bastions and counterguards; large ravelins were to cover the central parts of the fronts of fortification and afford crossing fires on the ground before the bastions; while mortars placed on the faces of the work and on the barbettes at the angles were to discharge their missiles over the parapets. A ditch surrounds the whole, and its exterior side is made with a gentle slope from the bottom to the level of the natural ground in front, for the purpose of facilitating the sorties; the corresponding facility which the enemy might have for descending into the ditch being disregarded on account of the supposed impossibility of maintaining himself there under the hail of stones and shot from the works.

It was supposed that the detached wall, being covered as before mentioned, would present an impassable obstacle to the assailants; but an experiment made at Woolwich in 1824, proved the possibility of breaching it by a fire of shot and shells, directed over the parapet of the counterguard, from artillery of great calibre, at the distance of 400 yards from the latter work. The efficiency of the vertical fire, as it is called, of stones and shot from the works has also been controverted; and experiments have been made which seem to prove that the momentum acquired by the missiles in their descent would not be sufficient to do serious injury to a man on whom they might fall, if he were protected by a proper head-piece.

We now come to what is variously termed the polygonal, right-lined, German or Prussian system. It has of late years been much adopted by German engineers, but has never yet been tested by an actual siege. Instead of the ramparts of the enceinte being broken up into bastions and curtains, they follow the lines of the polygon and are flanked by projecting masonry works called caponnières, something like Vauban's tower bastions, or Montalembert's casemated batteries, from which they are taken. The lines of defence may be about 300 yards, so that placing the caponnière in the centre of the side of the polygon this may be taken at 600 yards. The caponnière, projecting about 35 yards from the exterior, will contain 12 guns in 2 tiers of casemates on each side, that is twice as many as an enemy can place in a breaching battery against it; and if built with an interior court for ventilation would be about 30 yards in width. The caponnière is covered in front by a simple counterguard, or by a strong ravelin, and its sides flanked by gun casemates in the enceinte, the ravelin being flanked in the same way, or by casemates at its gorge. The detached escarp has commonly been employed in this system, of which perhaps the best example is Fort Alexander at Coblentz.

Besides these already mentioned, many ingenious systems have been advanced at various times, among which may be mentioned one by Lieut. Cook, late Professor of Fortification at Addiscombe College; Mr. Bordwine's system, and, still later, a further development of this latter by Mr. Fergusson. Mr. Fergusson's system has of late received so much notice from the able manner in which he has advocated it, that it would appear to require some description in this place; but in the limits of this article, though some idea might be given, it would be impossible to do it justice; the reader is therefore referred to 'Fergusson's System of Fortification.' It may be remarked, however, that ingenious as it undoubtedly is, and remarkable as are some of the ideas propounded, it has not attracted any large amount of support from engineers either in England or on the Continent; and though the author appears to attribute this principally to professional jealousy, &c., it must be acknowledged that it could hardly be carried out in its entirety, nor would it be likely to fulfil his anticipations. It is necessary to guard against the idea, in discussing the system, that the Russians employed it, and with such great success, at Sebastopol. This confused idea appears to have originated from the fact that Mr. Fergusson proposes a huge mound of earth divided into numerous parallel ramparts, and that the Russians used earth-works, though the former proposes to sprinkle his ramparts pretty freely with casemates, and the latter used unrevetted earthworks because they could make no other, and followed the ordinary plans which have been followed for centuries in field fortifications or entrenchments; never raising tier above tier of guns, except where occasionally one battery erected behind and on considerably higher ground fired partially over one in front. This may be easily seen by a very cursory inspection of the plans. The immense duration of the siege of Sebastopol is easily accounted for, when we remember that a large and powerful enemy, never numerically much inferior and occasionally superior to that of the allies, was defending in a naturally very strong position one of the largest and best supplied arsenals in the world, from which they obtained guns and ammunition in greater numbers, and of larger calibre, than the allies had, almost to the last, to bring against them; that their rear and communications were open, so that casualties could be replaced; that they had a powerful fleet in their well-fortified harbour, and a great number of the ships of which being sunk supplied them with artillerymen; that they had a large army of observation in the field constantly harassing the allies, and threatening, by such sorties as at Inkermann, to raise the siege; and, lastly, that even on the approach of the allies on the south side, they had sufficient permanent works, as the crenelled wall on the west, the central bastion, the Malakoff tower, &c., with their ships, to make a *coup de main* hazardous, if not impracticable, and thereby by obliging the allies to make batteries and bring up guns to destroy these, giving themselves time, which they certainly availed themselves of, to erect counter batteries and perfect their defences.

It is scarcely probable that any existing fortresses will be demolished for the sake of the advantages which would result from a re-construction according to any of the methods which have been proposed since the time of Vauban; but, on any future occasion which may present itself for fortifying a town or military post of importance, it may be found convenient to adopt some improvements in the construction of the works. Thus, the general system of Vauban, with the modifications proposed by Cormontaingne, being retained as the basis, casemates, like those of Montalembert, might be formed in the re-entering angles of the enceinte or tenailles, and detached walls or galleries for musketry in some of the dry ditches: detached ravelins, as proposed by Bousmard, may be constructed beyond those of the ordinary kind, in order to prevent the enceinte from being breached at the first crowning of the glacis; and a direct defence of the covered way may be obtained from galleries formed within, or on the exterior of, the parapets along the faces of the works.

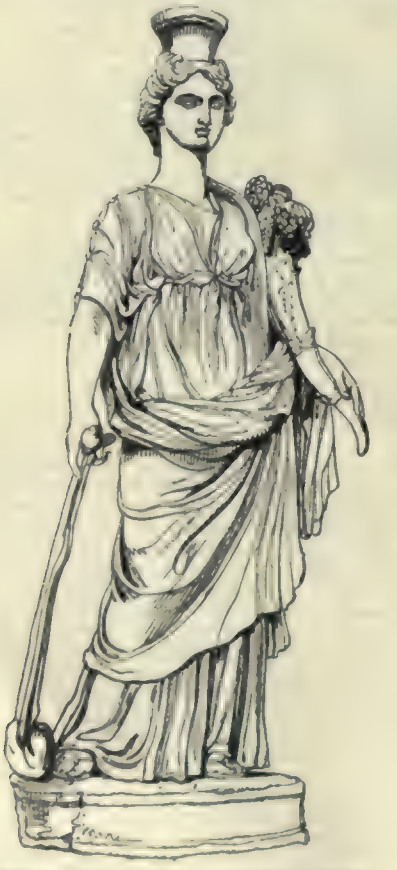
In the open attack of a fortified place it is evident that the loss of life would be so much the greater as the defensive works are stronger and better combined; and, in consequence, the necessity of making the approaches under cover to the last moment of the siege, would become more urgent.

For the works occasionally constructed beyond the glacis of a fortress, see FLÈCHE, HORN-WORK, LUNETTES, and TENAILLONS.

Of the works which fall under the denomination of field-fortifications, BRIDGE-HEADS have been already mentioned; REDANS, REDOUBTS, and STAR-FORTS are described under those words; and the combinations of works which serve for the protection of armies, that is, *Field Fortification*, under LINES OF ENTRENCHMENT. Small forts with bastions are frequently employed in field-fortifications: their plan is similar to that of the enceinte of a fortress; but they differ from the latter in their size, in having low relief, and in the sides of their ditches being unrevetted, or only faced with sods.

The limits of an article such as this, will only permit of the most cursory notice of this complicated and intricate subject: the reader is therefore referred for further particulars to the standard works, such as Bousmard's 'Essai Général de Fortification;' Dufour's 'Mémorial pour les travaux de guerre;' Carnot, 'De la Défence des places fortes;' Sir John Jones' 'Sieges in Spain;' Belma's 'Sieges in Spain;' St. Paul's 'Traité de Fortification;' 'Aide Mémoire (English) to the Military Sciences;' Capt. Macauley, R.E., on 'Field Fortification;' Lieut.-Col. Jebb, R.E., 'Treatises on Defending Outposts,' and 'The Attack;' Straith's 'Fortification,' revised and re-arranged by Cook and Hyde, 7th edition, &c.

FORTUNE (Fortuna), in the Roman mythology, was a goddess who was supposed to dispose, at her caprice, of the destinies of men; corresponding in a great measure to TYCHE of the Greeks. This deity did not figure in the more ancient systems of theosophy; Homer does not mention Fortune in the Iliad, but refers the events of this world to the decrees of Jupiter and of Fate. Fortune however was worshipped in Italy of old; by the Etruscans at Volsinii, under the name of Nursia; by the Latins at Præneste; and by the Volsci at Antium, where a splendid temple was dedicated to her, in which a sort of oracles was delivered. She had several temples at Rome. As directing the events of life she was represented with a rudder; with a ball as typical of the instability of fortune; and with a cornucopia and occasionally with the modius as diffusing abundance and prosperity. We give an engraving of a statue of Fortuna, in which all these attributes are united: the original, a small but very graceful marble statue (3 feet 1 inch high) is in the Third Greco-Roman Saloon of the British Museum. (Lactantius, *Instit.* i. 29; Horace, *Od.* i. 35; Martial, *v.* ep. 1.)

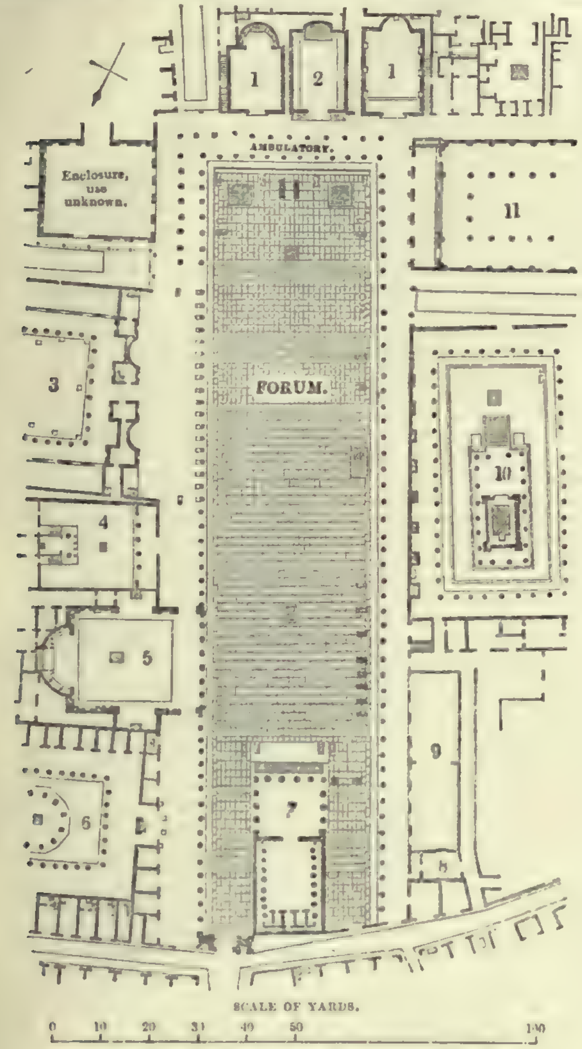


Fortune. From the statue in the British Museum.

FORUM, a large open space in ancient Roman cities (corresponding to the Agora of the Greeks), usually surrounded with public buildings, where the citizens met to transact business, and where, previous to the erection of Basilicæ, causes were tried. From this last circumstance the word forum is used metaphorically for a place of justice. Nardini is of opinion, though without any show of authority, that the first forum, or Forum Romanum, at Rome, was placed on the Palatine Hill. The Greeks made their Agora square, with a double colonnade, or ambulatory, above and below; but in Italy the width of the forum was made less than the length by a third, and the columns set wide apart, as the gladiatorial shows were formerly given in the forum. (Vitruvius, lib. v. 1.) The Roman fora were of two kinds, Fora Civilia and Venalia: the former were for law and political affairs, the latter for the purposes of trade. Rome contained nineteen fora of importance,—the Forum Antonini, Archemorium, Argentarium, Augusti, Boarium, Cæsaris, Cupidinis, Nervæ, Olitorium, Piscarium, Piscatorium, Pistorium, Romanum, Sallustii, Suarium, Tauri, Trajani, Transitorium, and Vespasiani. Of these the Forum Romanum, Nervæ, Trajani, Boarium, and Piscatorium, alone retain any traces of the splendid edifices with which they were once adorned. The Forum Romanum is situated in a narrow valley, not far from the Tiber, between the Palatine and Capitoline Hills. It sweeps round towards the Fora of Cæsar and Augustus, which are between it and the larger Fora of Nerva and Trajan, all which, looking at their relative situations, were no doubt connected with it on the north. On the south it extended nearly to the Fora Boarium and Piscatorium, which were near the Pons Palatinus, now called Ponte Rotto: its exact limits are, however, uncertain. It was decorated with temples, statues, basilicæ, curiæ, rostra, triumphal columns, and arches, which usurped the place of shops, schools, and even private houses, that originally stood in this forum. In the forum were the rostra, or pulpits, decorated with the beaks of ships, whence the orators harangued. According to Appian, the rostra were placed in the middle of the forum; and he states that Sulla caused the head of young Marius to be hung up before the rostra in the middle of the forum. Varro, in his fourth book, 'De Lingua Latina,' places the rostra before the curia, which was near the Comitium, so that the orators would stand with their faces towards the capitol; but Plutarch, in speaking of the Gracchi, states the reverse to be the case.

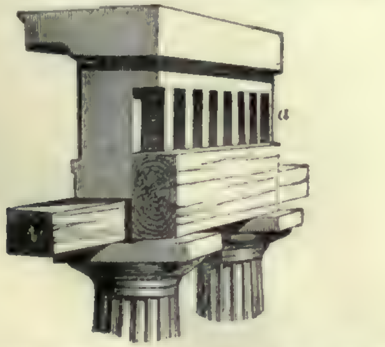
The Comitium was placed near the Curia; three columns of the former, commonly called the Temple of Jupiter Stator, still remain. Nardini places on the side of the Palatine Hill, in succession, the Fabian Arch, Græcostasis, Senalum, Basilica Opimia, Ædicula of Concord, Temple of Romulus, Temple of the Dii Penates, Curia Ostilia, near which was the Comitium, Basilica Portia, Temples of Julius Cæsar, and Castor and Pollux. On the side towards the Tiber stood the Temples of Jupiter Stator, Temple and Atrium of Vesta, Basilica Julia, house of Lucius Tarquinius, and the Temple of Victory. On the side of the Capitol were the Arch of Tiberius, the temples of Saturn, of Concord, and of Vespasian, the school of Xanthus, the Arch of Severus, which still remains, and the Tullian Prisons. On the north side of the forum were the office of the secretary to the senate, and the Basilica of Paulus Emilius. There are, however, but few remains existing of a small number of these numerous buildings, and the greater part have entirely disappeared. A single monumental column stands near the Comitium, called the Column of Phocas. Besides these buildings, there are remains of the temples of Fortune, Jupiter Tonans, Jupiter Capitolinus, and the Tabularium, though these are perhaps not within the boundaries of the forum. (See plates in Nardini's 'Rome,' vol. ii., lib. v., c. 1.) A very beautiful restored view of the Forum Romanum was made by Mr. C. R. Cockerell, R.A., and a reduced view was engraved and published, with his permission, in the second volume of the 'Pompeii,' published by the Society for the Diffusion of Useful Knowledge, to which we refer our readers for an accurate notion of the splendour of the accumulated architecture of the Forum and the Capitol, and its vicinity.

The forum at Pompeii was constructed in the Greek style, and has many Greek features. It is oblong, surrounded on three sides with rows of columns, forming, with the advanced columns of the various buildings, a colonnade or ambulatory; above this there was a second ambulatory, if we may judge from the remains of stairs at several places at the back of the colonnade. The fourth side of the forum is inclosed with two arches placed on each side of a large hypæthral temple, called the Temple of Jupiter. On the west side are the prisons and the granary with an enclosed court before it and the prisons; the Temple of Venus and the Basilica; and on the narrow side, opposite the Temple of Jupiter, are three buildings generally considered to be the Curiæ and Ærarium: on the east side is an enclosure, the use of which has not been determined, the Chalcidicum [CHALCIDICUM], the Temple of Mercury, the Senaculum, and a building supposed to be a large eating-house, generally known by the name of the Pantheon, in front of which are the Tabernæ Argentariæ. The enclosed area of the forum was paved with large square pieces of marble, and the sides of the area were adorned with statues. Opposite the curiæ and a short way from them is a small triumphal arch. The forum was closed at night with iron-barred gates, and it does not appear that chariots were admitted into it, as the pavement of the streets terminates at the back of the colonnade. The columns of the ambulatory are of the Greek Doric order, and were being restored in the same style, though with better materials, at the time the city was destroyed. The columns were aræostyle, and the architraves were most probably of wood, as we may infer from their being destroyed, while the frieze and cornice of stone remain.



Plan of the Forum at Pompeii.

1, 1, Curia; 2, Ærarium; 3, Chalcidicum; 4, Temple of Mercury; 5, Senaculum; 6, Pantheon; 7, Temple of Jupiter; 8, Prison; 9, Granary; 10, Temple of Venus; 11, Basilica.



Construction in wood and stone of the aræostyle portico of the Forum.

a, holes for the joists of the upper floor.

FOUGASS, a small military mine, formed by sinking in the ground, to a depth not exceeding 10 feet, a box of powder, or one containing two or more loaded shells. The train of powder by which it is to be fired is contained in a linen tube, and this is frequently protected by being placed in a case of wood. A trench is cut in the ground to receive the train, but it is subsequently filled up.

Fougasses are sometimes employed in the defence of field forts, and then they are formed under the glacis, or on the counterscarp, at the points where the assault is expected: in this case generally the train of powder is conveyed under ground to the counterscarp of the ditch, where the fire is to be applied; but occasionally this is done in the interior of the work, the train being then made to pass under the bottom of the ditch.

Sometimes a fougass is used to destroy a small work, in which case it is sunk within the mass of the rampart or parapet.

A stone fougass or rock mortar is formed by excavating a shaft in the ground at an inclination of about 45°, and about 6 feet deep. A charge of powder of 50 or 60 lbs. is placed at the bottom of this, with a shield of wood 6 inches thick placed on it. The charge of stones is then thrown in. There may be about 4 cubic yards of stone, each stone or pebble not being less than half a pound in weight; a sufficient body of earth being placed vertically over the stones to make them take effect in the right direction. The charge is fired as an ordinary fougass.

FOUNDATIONS. The surface which immediately supports a building is technically known under the name of its *foundation*, whether it be natural or artificial; and from this function arise the laws applicable to this particular branch of the arts of construction, namely, that, howsoever formed, the foundations of a building must not be susceptible of movement of any description whatever, after they shall have assumed the statical condition they were designed to assume when loaded to the fullest extent. It follows from the infinite varieties of the resistances of the apparent portions of the earth's crust under the various forces exercised by a building, that very great differences must prevail in the modes of dealing with foundations; and in addition to the difficulties attending this part of the science, other, and perhaps more serious ones arise from the circumstances under which the foundations themselves may have to be prepared or executed. They may, indeed, either be prepared in the open air, or under water, or without disturbing to any serious extent the natural compressible subsoil; and they may be either wholly or partially natural or artificial.

Natural foundations require little description here. They exist wherever the site upon which a building has to be erected is situated upon a homogeneous formation of sufficient thickness to render any lateral displacement of the bearing strata impossible. The only danger, indeed, of this class of foundations would arise from the tendency to such movement, and it therefore behoves the engineer or architect to inquire very carefully into the conditions of substratification, and of subterranean water-flow, which might be likely at any future time to develope changes in the statical conditions of the surface strata. Should there not exist any lower moveable beds, there are few rocks which may not be unreservedly trusted as foundations. Gravels, coarse sands, loams, and clays may equally be adopted, provided they be not unconformably deposited on the edges of a highly inclined basin of a rocky nature. Even soft alluvial deposits, when prevented from spreading laterally, may at times be resorted to as natural foundations; but both in this case, and in the one in which diluvial formations occur on the edge of highly inclined strata, care must be exercised in the manner in which they are used. In fact, any stratum which will support a vertical weight equal to 30 pounds upon the superficial inch without sensible compression, *after a month's trial*, may be considered fit to serve as the foundation of a building: provided always that there be no subjacent moveable strata. The lower courses or the footings of the building itself must therefore present a bearing surface proportionate to the resistance to compression likely to be met with in the natural foundations. Even when the latter are distinctly susceptible of vertical compression, there is, however, less danger from this cause than from their tendency to lateral displacement, especially when they are of a tolerably uniform character; and it is for this reason that it is essential to isolate the bearing surface of any important structure from any irregular or permeable strata whose particles might be displaced by any natural or artificial changes in the hydrographical conditions of the locality. As very few natural foundations are to be met with whose surfaces are sufficiently level to receive the footings of a building, it has been customary of late years to fill in their depressions (to regularise them, in short) by spreading a bed of concrete over them; and it may be received as a tolerably safe general rule, that every rock, gravel, or clay formation will resist a vertical crushing weight which may safely be brought upon the surface of the concrete itself. Of course the resistance of that material will depend upon the nature of the lime or cement of which it is composed; but as, under ordinary circumstances, the concretes made with the moderately hydraulic limes fulfil all the requisite conditions, its resistance may be taken as the limit of the safety load it is desirable to bring upon a natural foundation. Vicat estimates it at about 30 pounds per superficial inch, after the lime has had time to set fairly.

Foundations may be said to be *partially natural*, when the inequalities of level of the ground on which the building is about to be erected are so great as to require that they should be compensated for by the interposition of some extraneous substance; or when the resistance of the natural surface would not be sufficient to enable it to support the superincumbent weight. When the former of these conditions prevails, it is essential that precautions should be taken to obviate any danger which might arise from the movements of a different nature likely to occur in the natural and in the artificial portions of the foundations. When the latter condition occurs, the modes of dealing with the foundations so closely resemble the ones it is advisable to adopt with the more exclusively artificial class, that they are at once referred to it. Strata which are exposed to lateral displacement frequently require the execution of works of so complicated a nature, before a building can safely be erected upon them, that they can hardly be considered to belong to the category of the partially natural foundations, even when the natural surface of the ground is but slightly altered.

Artificial foundations are those which are required when the strata occurring at the surface of the ground, upon which it is proposed to erect a building, are of a highly compressible or of a moveable nature, and of such a thickness as to render it dangerous to bring a heavy load upon them, and impossible to remove the bulk of the soft material which thus covers the harder substratum. These conditions usually occur in situations wherein the surface stratum is composed of alluvial matter, or upon the shores of the sea, of lakes, rivers, or in morasses, peat deposits, &c., and the ordinary difficulties attending the execution of foundations in such positions are increased by the necessity for dealing with the water which accompanies those deposits. The nature of the works required to form artificial foundations will therefore depend mainly upon the question as to whether or not it be necessary to execute them in the open air; and when it is possible to avoid laying dry the surface to be operated upon, it becomes important to consider the effect of the water upon the durability of the materials which enter into the composition of the artificial foundations themselves.

In such cases as those which occur near the embouchures of the European rivers, where in fact a fine alluvial clay, sufficiently mingled with sand to allow water to permeate the mass, commonly overlies a more ancient and denser geological formation, it is customary to form artificial foundations by means of piles or baulks of timber, which are driven vertically, wherever it is possible so to do, through the alluvious into the harder substratum. Sometimes these piles act merely by the compression they produce upon the ground into which they are driven, but as a general rule they serve to support the superincumbent weight, somewhat in the manner in which pillars would do in the open air. In the former of these cases, the number of the piles is the most important consideration; and, as the resistance they have to overcome in driving is insignificant, their shape is a matter of indifference: nay, it may happen even that (as near l'Orient, where artificial foundations have been established upon soft mud of practically indefinite thickness) it would be desirable to drive the piles with their butt end downwards; —to trust, in fact, to the friction upon the sides of the pile for the limited degree of stability to be thus obtained. In the latter case, or when the piles have to transmit the weight to the resisting substratum, it is necessary to proportion the length and the transverse section of the piles to the load, and to cut the driving end in such a form as to ensure their entry into the bearing stratum. As they have to overcome considerable resistances in the course of their descent, they require to be shod either with cast or wrought iron, and to be hooped or bound with iron at the heads. The necessity for the latter precaution increases with the violence of the blows struck upon the head of the piles; and it has been even found that when the Nasmyth's hammer has been used, the frequent heavy blows at times either develope so rapid a compression of the fibres as to set the piles on fire, or they beat the heads into a spongy mass. The piles are also occasionally exposed to be split, if the shoe should encounter any very hard substance in its descent.

The description of wood used for piles ought to be a matter of serious consideration to the architect or engineer. Fir timber resists alternations of dryness and moisture better than either elm or beech (which are the other woods employed for this particular purpose); but if it should contain much sap at the time of its being driven, the fir will rapidly decay. Beech resists the constant action of water, but if it should be exposed to alternations of dryness it will rot; whilst elm timber presents an intermediate degree of durability under those circumstances. The boring worms constitute, it may be observed, one of the most fatal sources of danger to piles driven in the districts where these creatures abound, and they have naturally exercised the ingenuity of both theoretical and practical men to devise some protection against them. Sometimes the whole surface of the piles is, for this purpose, studded with copper nails; at others the wood is steeped in a variety of solutions, such as creasote, or corrosive sublimate; but unfortunately it does not seem to be possible to depend on the successful results of any of those operations. [PHOLADIDÆ, *Teredo*, in NAT. HIST. DIV.] It is said that the *green heart* is the wood which is the most free from the attacks of these destructive creatures, and that creasoting ordinary timber to some extent guarantees its immunity.

Piles are known by distinct names, according to the position they may occupy in a foundation. Thus, the piles which define the limits of the ground to be inclosed are known as the *guage piles*. When the space between the guage piles is filled in with other piles of the same scantling, the latter are called *close piles*; but if they should be of less thickness, they are called *sheet piles*. All these pieces of timber are tied together with horizontal *wales*, or by cross braces. Generally speaking, in foundations intended to support heavy structures upon very soft strata, an inclosure of either close or sheet piling is driven all round the intended situation; and then isolated piles, of about 12 or 14 inches square, are driven at distances of about 3 feet from centre to centre. Upon the projecting ends of these piles sleepers are laid, and close planking is fixed to them. At the present day, the heads of the piles and the sleepers are bedded in concrete, which is carefully rammed up to them, and levelled to receive the close planking. In many cases, also, in England, the planking is replaced by a layer of Yorkshire landings. In driving the piles, it is desirable to work from the outside, inwards; because in that manner the compression of the ground produced by the mere act of driving the piles tends to increase the solidity of the bearing surface. No notice is taken, however, of the additional strength thus obtained; but the load to be brought upon the piles is calculated as though they were intended to support the weight in the air without any lateral support. Evidently, under these circumstances, the safe load a pile may bear will depend upon the length of the pile itself. In practice, this consideration is frequently neglected, and constructors content themselves with the rough general rules, "that the diameter of a pile should be $\frac{1}{20}$th of its length, and that the safety-load of such a pile should be about 400 lbs. on the superficial inch of the sectional area." Under no circumstances, however, should piles of less than 7 or 8 inches in diameter be used.

The piles themselves are driven by several descriptions of engines, according to the resistance to be overcome, and also according to the magnitude of the work. If the piles have to be driven in soft uniform ground, such as that which is usually met with in the Fen districts of the eastern counties, or in Holland, the old-fashioned ringing engine will suffice; but if the ground should become gravelly, it may be necessary to use the heavy monkey worked by a crab, or the Nasmyth's hammer, or the pneumatic pressure upon the system of Dr. Potts's patent, or upon that of the adaptation of compressed air; although perhaps the two last-named methods of forming foundations are more particularly applicable to tubular foundations than to piled ones. The weight of the monkey used in ordinary ringing engines is about 12 cwt., and the fall attainable is about 4 feet or 4 feet 8 inches; in the case of pile-engines worked by machinery, the weight of the monkey varies from 16 to 22 cwt., and the fall ranges between 12 and 18 feet; in the Nasmyth's hammers, the monkey is made from 32 to 45 cwt., but the fall does not exceed 2 feet 6 inches. But whatever may be the machinery adopted for the pile-driving, that operation must be continued until the pile refuses to advance under a certain effort, dependent upon the nature of the effort itself. This is usually fixed, empirically, as follows: Assuming that the weight to be brought upon each pile is 25 tons, the pile is considered "to refuse" when a series of thirty blows from a ringing engine, with a monkey of 12 cwt. falling through a height of 4 feet, will not cause it to advance more than half an inch; or when a series of ten blows has been given by a monkey of the same weight worked by a crab, and falling through a height of 12 feet; or when a series of seventeen blows from a Nasmyth's hammer, weighing 34 cwt., and falling through 2 feet 6 inches, has been given, without producing a greater advance.

In the system of foundations known by the name of Dr. Potts's patent, the piles at times act in a manner which makes that word inapplicable to them; for they become, indeed, wells, or tubes, subsequently to be filled in with concrete. Thus Dr. Potts used occasionally small piles of wrought iron; but at other times, and as a matter of choice, he used large ones of about 6 or 7 feet in diameter; but both the large and the small piles bore upon a sharp continuous edge, instead of upon a point, as in the case of ordinary solid piles. The descent of the tubes was produced by the application of pneumatic pressure; there was fitted upon the head a cast-iron plate, the air was then withdrawn from the interior, and the pressure of the atmosphere upon the cap, forced the tube into the ground, until the air in the interior was compressed sufficiently to resist the pressure on the cap. The earth was then removed from the interior of the tube, and, when the latter had been sunk deep enough, the interior was filled in with concrete.

A curious method of founding bridges upon deep sands is used in India, to which attention may be called here. It consists in sinking brick linings in all respects like those used in wells, and these linings are sunk in precisely the same manner. The brick-work is built upon a wooden curb, and the ground in the interior and upon the curb is then removed, just as is done in well-sinking; and the interior is subsequently filled in with rubble or with concrete. It is said that the Indian divers carry on the operations of sinking these linings under great depths of water. A good description of the mode of executing the Indian well foundations will be found in the 'Excerpt Minutes of the Institution of Civil Engineers,' for May 12th, 1857, and in those for February, 1842.

The greatest improvement which has lately been introduced in the method of founding important structures, in situations wherein the natural surface of the ground was not adapted to receive them, is, perhaps, the system adopted in founding the bridges of Rochester, Saltash, of the Quarantaine at Lyons, Macon, Bordeaux, Kiel, and Szegedin. In these cases, large tubes were placed in the positions designed for the piers, and an air-tight lock, or chamber, was formed at the top, through which the workmen and the materials were passed. The earth within the tube was dredged out as far as possible by the ordinary processes; and, the various valves being closed, the water was forced through a syphon pipe by compressing the air in the interior. A pressure of one atmosphere (above that of the external air) was usually found to be sufficient for this purpose; but, in order to prevent any rising of the water, or any blowing of the sand, the air in the interior of the cylinders was compressed to about three atmospheres. The workmen then passed to the bottom of the seating, and removed into buckets, which were extracted through the air-locks, the earth which rose above the edge of the tube; and when subsequently the air in the interior was reduced to its normal pressure, the mere weight of the tube and the machinery upon it caused the tube itself to descend in a manner analogous to the descent of a well-curb. In the Rochester and Saltash bridges the tubes were sunk through the permeable, moveable strata until they reached the rocks able to constitute a natural foundation. In the Szegedin Bridge, however, the tubes were merely sunk so far as to obviate any danger of the undermining of the foundations by the action of the river, and a piled bottom was formed in them to receive the concrete. In some cases the tubes were formed of wrought, in others they were of cast iron.

One curious observation was made on the occasion of an accident to a tubular foundation of this description at Macon. A barge drove against a cast-iron tube, and broke it; and on attempting to repair the damage so done, it was found that, although the upper portions of the concrete filling (which had been executed with mortar made of the best hydraulic lime) had set, nevertheless the portions which had been immersed in deep water had not commenced to solidify. It would thence appear that there are some hitherto unexplained conditions, with respect to the solidification of mortar under great hydraulic pressure, to which the attention of engineers requires to be directed.

The various descriptions of artificial foundations mentioned above, are supposed to be continued to such a height above the water-line of the neighbourhood, as to allow the superstructure to be erected in the ordinary manner. In tidal rivers or in streams exposed to floods and sudden changes of level, it is however often desirable to carry the bottom courses of the substructure to such a depth below the normal water-line, as to obviate any danger from the removal of the sand, or earth beneath them. If the depth requisite for this purpose should not exceed 8 feet, a simple dam of impermeable earth will suffice to protect the works, and to allow the workmen to lay the masonry in the dry. But in such rivers as the Thames, where the tide rises from 14 to 18 feet, it becomes necessary to resort to the use of COFFER DAMS when it is required to carry the springing courses to any considerable depth below the low-water line. A description of these structures has already been given; as also has been given a description of the CAISSONS so much employed in the course of the last century; but it may here be added that the practice of engineers at the present day is decidedly to avoid the execution of either of these methods of forming artificial foundations, on account of the expense of the former, and of the uncertainty of the latter. The system now most generally adopted is to inclose the site of the intended structure with a close sheeting, to dredge out the interior very carefully, and to fill in the space thus formed with piles or concrete. Evidently the stability of a foundation of this description must depend upon the depth to which the protective sheeting is driven; it must be carried below the extreme range of the scouring power of the river.

Of late years cast iron has been very successfully substituted for wood in the piles and plates, or sheeting, intended to inclose an artificial foundation. Examples of this description of structure are to be seen at the Blackwall Railway Quay, the Victoria Docks, &c.

When buildings are to be erected upon soft compressible peat, and the hydrographical conditions of the district are not likely to be changed, it may suffice to inclose the whole area of the foundations with a piled or plated sheeting, and to replace a portion of the peat by a layer of sharp silicious sand. In fact sand to a great extent acts like an incompressible fluid under a heavy load, and the effort exerted upon one portion of the surface is distributed over the whole, provided the sand be prevented from spreading. Care must, however, be taken that the subjacent peat should not be subject to lateral displacement, and that whatever compression may take place should forcedly take place in a vertical direction. The seatings of some of the German railways, carried over the immense peat bogs of that country, are occasionally thus formed upon pillars of sand, formed by filling large square holes sunk through the body of the peat itself; and in some other instances holes were bored through the peat, and subsequently filled in with sand.

A method of forming artificial foundations was formerly much resorted to in the neighbourhood of London, and in other analogous positions, in which the superstructure was carried upon timber platforms so designed and put together as to distribute the weight over a very large area. The success of this system depends, firstly, upon the strength of the platform, which must be sufficient to resist the partial actions of the load; and secondly, upon the durability of the platforms themselves. If any change in the conditions of the moisture of the ground should take place, by improved drainage, or otherwise, the timber may rot, and of course the building erected upon it will be dangerously affected. This danger, it may be added, is far from an imaginary or theoretical one; for in the southern districts of London the changes made of late years in the sewerage have so modified the ordinary state of the surface strata, that the old timber platform foundations are generally decaying.

Whatever may be the description of artificial foundations used, or whatever may be the character of the natural foundations resorted to, it is essential that the weight of the superincumbent structure should be distributed in the most regular possible manner, over the whole bearing surface of the foundations. It is for this purpose that the best builders make a practice of carrying the lower courses of their structures, evenly, under all the walls, and of executing them with the largest and most homogeneous materials they can obtain. The footings, as these lower courses are specially called, are made wider than the upper work, and even when large openings have to be made in the elevation, the weight thus thrown upon the piers, by the sides of these openings, is distributed over the whole area of the footings by means of inverted arches. In countries where brickwork is principally used, and where cement is accessible, it is often customary to introduce, immediately above the footings, a deep band of brickwork in cement, which serves not only to tie together the mass of the wall, but also to intercept the capillary action of the materials of the upper wall upon the moisture in the ground. Where, however, this system cannot be carried into effect, it is essential that precautions should be taken to ensure the strength of the masonry in this part of the structure, and to distribute the effort exercised upon any one portion of it over the widest possible area by the use of the largest blocks in the footing courses. These courses, it may be added, should be made to project on either side of the vertical walls, and to present a number of sets-off proportionate to the weight and character of the superstructure. The width or projection of each set-off should in no case exceed the height of the course itself; but perhaps the most important general remark to be made upon this branch of construction is after all that the materials used in the footing courses should be of the hardest and most impermeable descriptions, and those which would be the least likely to decay under the action of alternations of dryness and humidity. The durability of a building in fact depends so much on the measures which may be taken to prevent the absorption of moisture by the foundations, that it is impossible to exaggerate the precautions to be observed in the selection of their materials. [LIMES; MATERIALS FOR BUILDING.]

FOUNDING; FOUNDRY. Founding or casting is one of the mechanical arts which embraces all the operations of reducing ores, and of smelting and casting metals. There are various branches of the art; and some difference prevails in the minor details of the processes —as in iron-founding, brass- and bronze-founding, cannon-founding, type-founding, and bell-founding. The finishing operations of chasing, burnishing, plating, &c., are also parts of the founder's art. Under the names of the chief metals, as well as in such articles as BELL, CANNON, TYPE, &c., various processes of founding are described; in the present article we shall treat of the general features of the art, especially in connection with large iron castings.

It is certain that the art of founding is of very high antiquity. From the passages in the Old Testament referred to under BRONZE, we find that Tubal Cain was skilled in working in metals, and that the arts of metallurgy were known and practised very extensively by the early Israelites. The extent to which metal-working was carried on by the ancient Egyptians, Assyrians, Phœnicians, Greeks, Etruscans, and Romans, and the excellence to which it was occasionally carried in the fine arts, are too well known to need further observation in this place: a general history of it, as a branch of sculpture, has already been given in the article BRONZE, which also contains some notices from the ancient writers on the different methods adopted of solid hammer-working, hammer-work in plates, and casting; as well as on the varieties and composition of metals. In all the practical points of ancient founding our information is however very limited; the writers of antiquity having confined themselves, generally, to a description of finished productions, and leaving us little or nothing by which we can judge of the mode of working.

It appears that furnaces of considerable size, and producing a great tonnage of metal, were constructed in this country as early as the reign of Elizabeth; but it was not till the beginning of the 17th century that there was effected any great change in the character and importance of founding. Prior to that date all the operations of melting, &c., had been performed by means of wood fuel; but the demand for various objects in metal was now so greatly increased that it was evident, first from the consumption of timber for the foundries, and next from the destruction of forests in consequence of the agricultural improvements which were taking place in various parts of the country, that this provision must soon prove insufficient to meet the wants of the trade. It was then that the attempt was made to bring coal into use; and it is curious at this time to know how much difficulty, first from ignorance of its real value in the operations of metallurgy, and then from prejudice against such an innovation upon the old habit of burning wood only (to which must also be added the interference with the interests of wood monopolists), was thrown in the way of its introduction. One of the earliest and most zealous advocates for its use, Dudley, had all his works destroyed, and was nearly ruined by the violence of his opponents; but at length the employment of coal was fully established; and from that time the rapid advance of the iron and other metal works of this country may be dated.

We have stated the chief reason for having recourse to the coal-mines for fuel to have been the apprehension that the supply of wood fuel would fail. It is important to bear in mind, however, that, but for this well-grounded fear, wood or charcoal would always have been preferred for many of the operations of metallurgy; from its being less objectionable, as regards its chemical composition, than coal. The iron that is smelted in Sweden by wood fuel is considered a superior article, and is much sought after; and the smelters in this country find it necessary to char or coke the pit and sea-coal which they use, in order to adapt it to the purposes required. [Coke.] We shall now glance rapidly at some of the operations in the reduction of the ores of the four metals which are produced and worked in the greatest abundance in this country—iron, tin, copper, and lead: referring the reader to the articles under the names of those metals for further details.

Iron is obtained from a very abundant ore in this country, namely, the common ironstone of our coal-measures. For the reduction of the ore to a metallic state it is necessary to add a certain quantity of lime, which acts as a flux; and it is worthy of remark that, while the ore itself from which the metal is produced, and the coal for smelting it, are found together, the limestone by which its reduction is facilitated usually abounds in the lower regions of the carboniferous strata. Sometimes, as in the great coal basin of South Wales, a bed of millstone grit capable of enduring the fire, and used in constructing the furnaces, is also found in connection or alternating with the iron ore and limestone. The first operation the ore undergoes is *roasting*. This is done in various ways, both in this and in other countries. Sometimes it is conducted in kilns, sometimes on the ground in the open air. The first method is by heaping the iron ore on a mass of ignited coal. In the other, a thick layer of ironstone, broken in pieces, is placed upon a bed of coal, wood, or charcoal (on the continent wood or charcoal is always used), 6 or 8 inches thick, and covering an area of several yards; upon this another layer of fuel is placed, and then another pile of ore, which diminishes both in area and thickness towards the top. The whole is then covered with small coal or charcoal dust till it reaches some feet above the ground. The lower stratum of fuel is then lighted, and by degrees ignites the whole mass. In the course of a few days the ironstone becomes cool, and the sulphur, arsenic, water, and inflammable matter being driven off, it is fit for smelting. It is then placed in a furnace, with fuel and limestone in determined proportions. At Dudley, in Staffordshire, for 2¼ tons of roasted ore, which affords a ton of cast metal, 19 cwt. of transition limestone are employed as flux. In the course of a few hours the whole runs down, and the iron is melted, and in that state is allowed to flow into furrows made in sand, where it forms what is termed *pig-iron*; or it is poured into moulds where it forms the various articles of cast-iron ware. There are various sorts of cast-iron, but it is usually divided into three classes relatively to its colour and qualities, which are in this country called *numbers one, two, three*; sometimes more descriptive names are given to the different qualities, as *smooth-faced*, *gray*, *white*, *forge pigs*, *ballast*-iron, &c., &c. Cast-iron is converted into *bar*-iron by smelting it by means of charcoal, when it is welded and hammered; of this there are also varieties, of which the toughest, called *stub*-iron, is used in forming fowling-piece barrels. It is made by inclosing old horse-shoe nails tightly in a broad iron ring, generally made of Swedish iron; a welding heat is then applied, and the whole mass is hammered till by degrees the nails and ring become completely united: it is then drawn into bars, which make an iron of peculiar closeness, toughness, and malleability. These matters are further treated under Iron Manufacture.

The best ore of tin is found in Cornwall. It is commonly blasted by gunpowder, and is procured in pieces of considerable size, which are stamped to powder by beams shod with iron: it is then well washed till the earthy particles are carried off, and the tin is fit for the smelting house. After being roasted in a reverberatory furnace, and again washed, it is a second time subjected to the furnace, being now mixed with small coal, and in some cases, with a small quantity of lime. The melted tin thus produced is at last placed in a small furnace and exposed to a very gentle heat, when the purest portion melts first and is drawn off. This is called *common grain tin*; and the inferior, which still contains a small proportion of copper and arsenic, is then cast into pigs called *block tin*. The finest grain tin is procured from the stream works of Cornwall. Good stream tin affords from 65 to 75 per cent. of the best *grain*. For the details of operation, see Tin.

The reduction of copper ore is made by several consecutive processes. The first is by calcining it, and when the ore is sufficiently *roasted* to oxidate the iron which it contains, it is melted. The melted metal is after a time suffered to flow into a pit filled with water, by which it becomes granulated. It then undergoes further heating, and what is called technically its *slag* (or scoria) is taken off, and it is again allowed to run off into water. After other nearly similar processes the copper is cast in sand, when it becomes solid, and in this state is called *blistered copper*. It is now fit for what is termed the refinery, and undergoes an operation called refining or toughening. This is an operation of delicacy, requiring great skill and care in the workmen. The refining is conducted in a furnace similar to the melting furnace; the object is to thoroughly purify the metal from any portions of oxygen, which is performed by adding charcoal to the copper while it is in fusion, and stirring it occasionally till it is judged to be pure. The chemical relations of this process are noticed under Copper. When tin is united with copper, it forms the compound called *bronze*. [Bronze.]

The greater part of the lead met with in England is procured from a substance called *galena*, in which it is found combined with sulphur. There are, however, other ores of lead. The galena, being freed by hammering it and by the hand from whatever impurities can be separated from it by those means, is broken up into small pieces, and after repeated washings is placed in a reverberatory furnace; but only sufficiently heated to drive off certain ingredients without melting the lead itself. The *roasting* being finished, charcoal is added till the reduction is completed. The lead, after the *slag* has been removed from it, is suffered to run out of the furnace into a pan, and being first skimmed is ladled out into moulds and left to cool. There are various methods adopted in different places and under different circumstances for procuring the metal from the ores: these will be found succinctly noticed under Lead.

The furnaces that are used in founding are chiefly of two kinds, and though strictly speaking both are *air* furnaces, yet they are distinguished as *air* or *wind* furnaces and *blast* furnaces. The first acts by a draught through a chimney; whereas in the other the air is forced into the body of the furnace by means of bellows. The forms and relative proportions of the different parts of the furnace, and particularly the size, elevation, and direction of the chimnies, and the dimensions and space of the flues when these are required, are of great importance; the volume and intensity of heat and consequent certainty of the operations depending in a great measure on the knowledge and science displayed in adapting the parts to each other. The chief points of difference between wind, blast, and reverberatory furnaces are described under Furnace.

Founding is practised either by melting or casting any quantity of metal in the solid, or with a core (by means of which the metal is preserved of a determined thickness or substance), or in plain casting. Before any object can be cast in metal it is necessary that a model of it be prepared. The models may be made of various substances; clay or wax, or sand with clay, are those usually employed, but they may also be of wood, stone, or any other material. Upon those models *moulds* must be made; these are commonly composed of plaster of Paris mixed with brickdust, sometimes sand, or sand with a mixture of cow-hair. For moulds for iron and brass work a yellowish sharp sand is preferred, which is prepared by mixing it with water and then rolling it on a flat board till it is well kneaded and fit for use. This process is called, in technical language, *tewing*. If the model is cylindrical, or of a form that admits of such a process, it is moulded or cast in two pieces; these two parts are then carefully joined together, and the edges or seams trimmed. This doubling is an easy and cheap mode of execution, and only requires care to be successful. For the smaller class of works, instead of melting and running the metal at once from a large furnace, earthen crucibles are used, into which the metal is thrown in small pieces: the crucible is placed in a strong heat in a close stove, and as the metal is melted and sinks more is added till the vessel is full. It is then lifted out by means of iron instruments adapted to the purpose, and the metal is poured from it into the moulds, in which channels or ducts for receiving it have been previously made. There is one great advantage in using crucibles; namely, that the metal may be carried in them to any part of the foundry, whereas in general it is essential to have the moulds and the furnace close together. It is obvious however that melting metal in crucibles can only be practised where the casting is on a comparatively small scale.

In noticing the different ways of casting, mention has been made of one in which a core is used, and which may require some explanation. The *core*, as its name denotes, is a part or portion situated within the body of the cast; and its purpose in founding is to form a centre to the work by which the thickness or substance of the metal may be regulated. In coring, the mould must first be made complete; into this, clay or wax, or any other fit substance or material, is then squeezed or pressed in a layer of uniform thickness; in large works it is usually from half an inch to an inch thick. This layer represents the metal. The mould, if in parts, is then to be put together, the above-mentioned layer being left within it; and into the open space in the centre a composition (usually of plaster of Paris with other substances mixed with it) is introduced, and made to adhere to, or rather is filled up to the clay or wax. This is the core, and it is often made to occupy the whole interior of the mould. When this is *set*, or dry, the mould is taken to pieces and the material which has been made to represent the metal removed. The mould is then again put carefully together round its core or nucleus, the two portions being secured from contact by stops and keys properly arranged for that purpose. It is now obvious that when the mould is placed, with its channels and ducts, to receive the metal, this latter can only enter the interstice or space between the outer *mould* and the inner *core;* and thus, by an ingenious and simple contrivance, the cast is insured of sufficient substance to answer every object required, with, at the same time, a great saving of metal and reduction of weight.

In all these operations it is essential that the mould and the cores be perfectly free from moisture; seeing that the sudden and violent expansion of air that is at all damp, upon the heated metal flowing into the mould, would cause it to burst, to the destruction of the work and the great danger of the workmen. In order to guard against this, the moulds and core are usually placed in an iron closet or drying-stove, in which large fires are constantly kept up, and from whence they are not removed till it is ascertained that they are perfectly dry, and just before they are required for the casting. The moulds and cores of works of large dimensions are usually strengthened with bars and hoops of iron, to prevent them from springing or changing their form during the drying, and during the necessary moving and shifting about in the foundry. All that is now necessary before casting is to cut the channels or ducts for the metal to penetrate easily and quickly into the mould; and to place the mould conveniently with respect to distance and inclination from the furnace. The first operation is easily performed; the founder takes care to distribute the channels, both in number and in their size (or width), according to the parts of his work into which he requires a greater or less volume of metal to flow, and also, if the object be of great extent or complicated form, that the different parts of the mould may as nearly as possible be filled simultaneously; it being most desirable that the whole *getto*, or cast, should be made before the metal in any of the parts has time to settle or lose its fluidity. Other channels are also made for allowing the air to escape as the melted metal enters the mould; these are called vents, and are very necessary where the works are on a considerable scale. With respect to placing the mould, it is only important to secure a sufficient inclination of plane from the mouth of the furnace to the mould that the metal may run easily and uninterruptedly, and not have time to grow cool and therefore sluggish. The usual method in great bronze works is to bury the mould in a pit a little below the level of the furnace, and by ramming sand firmly round it to insure its not being affected by any sudden or violent shock, or by the weight of metal running into it. When everything is ready, and the metal found to be in a state fit for running, the orifice or mouth of the furnace (which is usually plugged with clay and sand) is opened, when the metal descends, and in a few minutes the mould is filled. The metal is allowed to run till it overflows the mouths of the channels into the mould. The work is then left to cool, after which the mould is scraped or knocked off and the cast undergoes the necessary processes (such as cleaning, chasing, &c.) to render it fit for the purpose designed. The variations which the processes undergo, in treating different metals and manufacturing different articles, will be found noticed under Bell, Brass, Bronze, Cannon, Iron Manufacture, &c.

Among the most remarkable modern specimens of founding, for their vastness of size and weight, are the cylinders and cranks of the *Great Eastern* ship; the iron tables for some of the plate-glass manufactories; the bed-plates for the larger kinds of machinery; some of the mortars on which such large sums of money have lately been unprofitably expended; and the two unfortunate bells for the Westminster palace. As was said under Bronze, the largest castings for fine arts purposes are frequently not made in a single piece; thus, the largest bronze statue of modern times, the colossal figure of 'Bavaria,' 61½ feet in height, placed in front of the Rühmeshalle, near Munich (modelled by Schwanthaler and cast by Fras. Miller at the royal foundry), was made in many pieces; and the largest of those did not nearly equal in weight the masses of iron above adverted to.

We may briefly notice here a method introduced in 1859 by Mr. Jobson, for casting shells and other articles. The pattern is made with arms carrying pins or projections, entering sockets in the plate on which the casting-box is placed. When the pattern has been correctly adjusted upon the plate, the pins and the ends of the sockets are filed, so as to make the ends of the pins and those of the sockets coincide; this affords a test for the workman to judge of the accurate adjustment for each casting. To facilitate the introduction and removal of the moulding sand, apparatus is arranged whereby the sand is shovelled upon sieves, which are worked mechanically; the sand is damped and sifted, and is carried by a sort of Archimedean screw to the mixer, where fresh sand and other matters are added, and whence the sand is conveyed through another trough by a screw into a position to be used by the moulder. In instances where heavy casting-boxes are employed, a peculiar form of crane is used; it consists of a quadrant, a chain or band passing over the quadrant, and a train of rack-and-pinion work; by this agency the box is raised, lowered, and moved laterally, with much facility.

For the various processes to which metal is subjected after founding, see Chasing; Embossing; Lacquering; Soldering, &c.

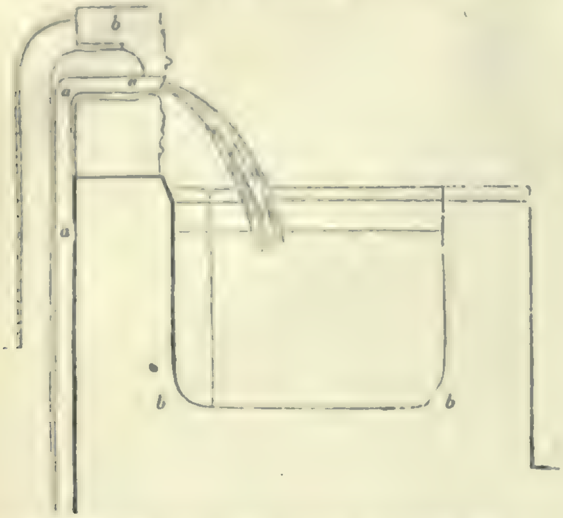
FOUNDLING HOSPITALS are charitable institutions, which exist in most large towns of Europe, for taking care of infants forsaken by their parents, such being generally the offspring of illegitimate connections. These institutions date from the Middle Ages, and were established for the purpose of preventing the destruction of children either by actual violence or by being exposed in the streets or highways. Among the Romans and other nations of antiquity, the exposure of children by poor or unfeeling parents was a frequent practice, and was not punished by the laws. After Christianity became the religion of the empire, it was forbidden by the Emperors Valentinian and Gratian. At the same time, the greater strictness of the laws concerning marriage and against concubinage, the religious and moral denunciations against unwedded intercourse, and afterwards the obligatory celibacy introduced among the clergy, and the severe penalties attending its infraction, all tended to increase the danger to which illegitimate infants were exposed from the sentiments of fear and shame in their parents. Child-murder and the exposure of children became nearly as frequent in Christian countries as they had been in Heathen times, only the parents took greater care to conceal themselves; and humane individuals in various countries began to devise means to collect and provide for the forsaken infants found in the streets. In this, as in other acts of charity, ecclesiastics stood foremost. At Rome, Innocent III., in 1198, when rebuilding and enlarging the great hospital of S. Spirito, allotted a part of it to the reception of foundlings, several infants having been found drowned in the Tiber about that time. This asylum for the "esposti," or foundlings, was afterwards enlarged and endowed by subsequent popes, and the institution was adopted by degrees in other cities. It was thought that by providing a place where mothers might deposit their illegitimate children in safety without being subject to any inquiry or exposure, the frequent recurrence of the crime of child-murder would be prevented. For this purpose a turning box was fixed in an opening of the wall in a retired part of the building, in which the child being deposited by the mother in the night and a bell being rung at the same time, the watch inside turned the box and took the infant, which from that moment was placed under the protection of the institution, was nursed and educated, and afterwards apprenticed to some trade or profession. Those parents who were in hopes of being able to acknowledge their child at some future time, placed a mark or note with it, by which it was afterwards known when they came to claim it, and it was then restored to them on their defraying the expense incurred for its maintenance.

In France, the philanthropist Vincent de Paul, the founder of the Society of the Missions in the first half of the 17th century, exerted himself to found an asylum for infants, which were at that time frequently left to perish in the streets of Paris. It was at first supported by private subscriptions, but afterwards was made a national establishment—"Hôpital des Enfans trouvés." Similar institutions were founded in other great French cities. Mortality appears to be very great in most foundling hospitals of the continent, owing to carelessness, mismanagement, or want of sufficient funds for the administration of those institutions. The infants are given out to cheap nurses in the country where a great number of them die. At the same time, it is remarkable that the number of illegitimate births has greatly increased over all Europe.

The principal objection that has been raised against foundling hospitals is, that they tend to increase the number of illegitimate offspring. In London, the institution of the Foundling Hospital, though it seemed to have prevented the exposure or murder of infants for a time, was found to produce such ill effects, that the object of the foundation was materially changed, and it is now a receptacle for illegitimate children on the application of the mother, who must prove the abandonment of it by the father, and whose character otherwise must be a good one. One distinction ought to be made, namely, that in countries where there is no legal provision for the poor, foundling hospitals appear to be more necessary, or at least less objectionable than in those where the mothers of illegitimate children, if unable to support them, have, like other destitute persons, the resource of the parish poor-house. It must also be observed that mothers of illegitimate children often neglect their unfortunate offspring, and are ill calculated by their habits to rear them up so as to make of them useful and honest members of society.

FOUNTAIN, a jet or jets of water, flowing either naturally out of the earth, or from structures formed by art. Artificial fountains consist of water flowing from vases, statues, sculptured ornaments, or architectural buildings combined with sculptured figures and other ornamental decorations.

Many ancient Greek cities were decorated with fountains. Pausanias informs us that Corinth was adorned with several fountains; and he mentions one in particular which stood near the statue of Diana, representing Pegasus, with the water flowing through his feet (ii. 3, 5). He describes another as consisting of a bronze Neptune seated on a dolphin, from the mouth of which the water issued (ii. 2, 8). Frontinus, who lived in the reigns of Nerva and Trajan, was superintendent of the fountains at Rome, and wrote a work, 'De Aquæductibus Urbis Romæ Commentarius,' in which he treats, among other things, of the distribution of the waters of fountains. The public fountains of Pompeii, some of which are almost perfect, evince the knowledge which the ancients possessed of the property of water to rise to its level, and their practical application of the principle.



Section of Fountain, from Pompeii, showing the ascending pipe, *a*, *a*, *a*.

Not only were the streets, but even the private houses of the Pompeians, decorated with fountains; and it appears that the ancients were acquainted with that law by which fluids may be made to ascend in a vertical jet to a height proportionate to the pressure which acts upon them.

Fountain, from the paintings of Pompeii.

One of the domestic fountains of the Pompeians is encrusted with coloured glass and shells. The fountain of water flowed from a large mask set on steps, placed within a large niche.

At Rome, the proper distribution of the rivers which flowed through her aqueducts was a matter of great importance, entrusted to the care of an officer of very high rank. It appears from Frontinus, who filled that office under the emperor Nerva, that the letting out of the public waters to private persons was a source of revenue. The right to a supply of water was strictly personal, not attached to houses, so that the supply was cut off at every change of ownership. The waters which had once been granted were sold by the superintendents, as they fell in, to the highest bidders. Those whose means or interest were insufficient to obtain a private pipe, were obliged to fetch water from the public fountains. ('Pompeii,' vol. ii. pp. 73, 74.)

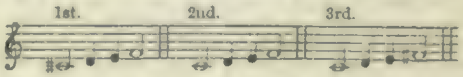
The number of leaden pipes found in Pompeii leads us to conclude that they were universally employed in fitting up the fountains of that city. Some fountains flowed through bronze figures, of which several are preserved in the museum at Naples. Specimens of the domestic fountains of the Romans (of marble) may be seen in the Græco-Roman Basement Room of the British Museum.

Some of the cities of Italy and the East are adorned with fountains, which are no less agreeable to the eye than useful to the inhabitants. Of all places, modern Rome is perhaps most abundantly furnished with this agreeable convenience, though this profusion is probably only a tithe of the luxury with which the ancient city was supplied. Many of the fountains of Rome are highly decorated, of great magnitude, and very varied in their mode of ejecting the waters with which they are supplied from the existing aqueducts. The fountains of Trevi, and the Pauline fountain at San Pietro in Montorio, are immense piles of architecture, the former highly decorated with sculpture. In Italy, almost every species of design which the imagination can form has been adopted by their ingenious artists in the construction of fountains. Many of those produced during the Medicean period are works of great artistic power. The fountains of the Saracenic architects, as shown in Spain, Cairo, and Constantinople, exhibited in their best day great fancy, lightness, and brilliancy of design, and a style singularly appropriate to the purpose and to the character of the surrounding buildings.

The city of Paris is well supplied with fountains, many of which are elegantly designed. The fountains of Versailles and St. Cloud in France, and the fountains at Wilhelmshohe near Cassel, were the largest in Europe prior to the construction of those at the Crystal Palace, Sydenham. Now the entire "system of fountains," as it is called, at this latter place may take rank, both as regards extent and brilliancy of effect, with anything previously produced.

London, though well supplied with water, has few fountains which make much pretension as works of art. During the past year, many small mural fountains, and a few standard fountains have however been erected in London and its vicinity, chiefly through the exertions of a society called the Metropolitan Free Drinking-Fountains Association. The primary object of this society is to erect as large a number of free drinking-fountains as possible, and with little loss of time. Eventually it is hoped that 400 such fountains may be erected in and around the metropolis. Utility rather than beauty, and economy of cost, are consequently leading principles in the preparation of the fountains of the association. In order, however, to combine a measure of ornament with utility, several designs have been selected, each of which serves as a pattern for a number of fountains; but few if any of the designs yet produced exhibit originality or fancy, and from the mode of reproduction the fountains show little individuality of character. Drinking fountains, similar in principle to these, were first introduced at Liverpool a few years back by Mr. Melly, a merchant in that city, who at his own cost erected several in the busiest localities. The example is being followed throughout the country, and already several hundred drinking-fountains have been erected. The majority of these are comparatively humble structures, but perhaps some of the most successful in an artistic point of view have been erected in provincial towns.

FOURTH, an interval in music, and to be enumerated among the discords; though it seems to have puzzled many writers on music, some of whom are much inclined to view it as a concord. [CONCORD.] Its ratio is 4 : 3. Of fourths there are three kinds: the *Diminished Fourth*, the *Perfect Fourth*, and the *Extreme Sharp*, or *Superfluous Fourth* (called also the *Tritonus*, from being composed of three whole tones). The first (C♯, F) is composed of a whole tone and two semitones; the second (C, F) of two whole notes and a semitone; and the third (C, F♯) of three whole tones. Example:—



FOWLING, the act or art of taking birds with nets, by shooting, snares, the use of bird-lime, or other devices. It is also sometimes used for the taking of birds with hawks and falcons, more properly called falconry. In Latin this sport is termed Aucupium. See Bargæus 'de Aucupio,' liber i., 'ad Franciscum Medicem Florent. et Senens. Principem,' 4to. Flor. 1566. Olina's 'Uccelliera,' 4to. Rom. 1684, is another work on fowling, the plates of which, representing the different modes of following the sport, are extremely curious. In English we have Blore's 'Gentleman's Recreation,' fol. Lond. 1686 and 1716; and 'The Experienced Fowler, or the Gentleman's Recreation,' 16mo. Lond. 1704.

FRACTIONS, COMMON AND DECIMAL. By a fraction is meant, in the first instance, a part of any magnitude. Thus, "three and a fraction" means three units and a part of a fourth. The next meaning of the term confines fractions, in an arithmetical point of view, to the *aliquot* parts or *submultiples* of the unit; which unit must therefore be divided into a number of equal parts, of which parts a certain number is to be taken.

Under the heads ADDITION, &c., will be found the various rules by which operations containing fractions are conducted. We shall here confine ourselves to fundamental points connected with the theory.

A fraction is thus denoted: $\frac{a}{b}$ means the quantity obtained by dividing a unit into b equal parts and taking a of those parts. If a be greater than b, it will obviously be necessary to divide more units than one, each into b equal parts, until enough have been subdivided to furnish the a parts required. It was usual, in English works on arithmetic, to call fractions in which a is less than b, *proper* fractions; and all others *improper fractions*; this absurd distinction is now beginning to be abolished. In the preceding fraction a is called the *numerator*, and b the *denominator*. The first term is correct, for a is the number of parts of a certain kind which are to be taken; the second is not quite so correct, for the denomination of which the number a is to be taken, is not b, but $\frac{1}{b}$; the bth part of a unit (not b units) is to be repeated a times.

On the whole, the terms *numerator* and *denominator* are very appropriate; but they are very long. Should they ever come into vulgar use, they will be shortened into *numer* and *denomer*; and it would be well if arithmeticians would do this for themselves.

The preceding fraction may be considered in several different ways. It is 1st, the bth part of a unit repeated a times; or, in common language, a-$b$ths of a unit; 2nd, the number of times, or parts of a time, or both, which a contains b; 3rd, the proportion which a is of b; 4th, the expression which ought to be written for a, on the supposition of that which was b units being made the unit. Thus $\frac{2}{5}$ expresses two-fifths of a unit, the part of a time which 2 contains 5, the proportion which 2 is of 5, and the expression which must be written for what is now 2, when that which is now 5 is made the unit. All these meanings, *except the first*, are perfectly intelligible when we write a fraction in which the terms are both fractional. Thus—

$$\frac{1\frac{1}{2}}{3\frac{2}{7}} \qquad \frac{6}{1\frac{1}{3}} \qquad \frac{\frac{1}{3}}{\frac{1}{4}} \qquad \frac{3\frac{2}{7}}{\frac{1}{7}}\text{ , \&c.}$$

may be thus explained. We can readily imagine the part of a time which $1\frac{1}{2}$ is of $3\frac{2}{7}$, the proportion which the first is of the second, and the expression which must be substituted for $1\frac{1}{2}$ when a larger unit is used, amounting to $3\frac{2}{7}$ of the present unit. But though we see clearly what is meant by dividing 1 into 3 equal parts and into 4 equal parts, what idea are we to attach to the division of 1 into $3\frac{2}{7}$ equal parts?

The generality of mathematical conceptions is frequently destroyed by the peculiar idiom of a language. The science of arithmetic requires the abolition of all those distinctions which depend on singular and plural, noun and pronoun, &c. Thus, when we speak of the answer to a problem being a number of feet (unknown), it is better to allow the word to imply a part of a foot, a foot itself, or a number of feet together with a part of a foot, than to repeat all those possible cases every time a number is to be mentioned. Again, when one particular phrase seems absurd, but another which is synonymous appears clear, we must either reject the former altogether, or attribute to it the meaning of the latter, and the second course is generally the more convenient. We now observe that the direction to "divide *one* into 10 equal parts" is the same as "find a part such, that ten of them shall make a unit." Now there is no absurdity in requiring to "find a part such that $3\frac{2}{7}$ of them shall make a unit," though it is inconsistent with our idiom to speak of "dividing 1 into $3\frac{2}{7}$ equal parts." The meaning of the phrase which is intelligible should then be extended to that which is not, or "to divide 1 into $3\frac{2}{7}$ equal parts" should mean that the part is to be found which repeated 3 times and $\frac{2}{7}$ of a time shall give the unit. And this must be extended even to the case in which the number or fraction thus obtained is greater than a unit. Thus in the fourth of the preceding fractions such a number or fraction must be found, that $\frac{1}{7}$th of it shall be a unit; that is,—

$$\frac{1}{\frac{1}{7}} \text{ stands for the number 7;}$$

and this must be repeated $3\frac{2}{7}$ times. The preceding considerations show that fractions with fractional denominators may be explained (without reference to any rule of reduction) by an extension of the definition which applies to integer denominators. The use of such an extension is as follows:—at present, algebraical students learn results which are perfectly intelligible with regard to whole numbers, or to fractions with integer terms, but of which they do not see the meaning when fractional or mixed terms are employed. In the latter case they trust to what they see in the former that their results will remain true; but they can have no distinct perception on this point until they have learnt to include every possible form of $\frac{a}{b}$ under one definition.

The fundamental property of fractions on which all others depend is this—that no fraction is changed in value by multiplying or dividing both its terms by the same number or fraction, that is,—

$$\frac{a}{b} = \frac{ma}{mb}$$

whatever may be the values of a, b, and m. This result should be studied in all the variety of its cases, from such as—

$$\frac{3}{5} = \frac{3 \times 10}{5 \times 10} \text{ to such as } \frac{2\frac{1}{3}}{\frac{17}{7}} = \frac{2\frac{1}{3} \times 1\frac{1}{6}}{\frac{17}{7} \times 1\frac{1}{6}}$$

There is another theorem which is much neglected in elementary works, but which is of considerable importance, namely, that if the numerators of two fractions be added for a numerator, and their denominators for a denominator, the resulting fraction must lie between the two from which it was derived. Thus of the three fractions,

$$\frac{2}{7}\text{ , } \frac{6}{11}\text{ , and } \frac{2+6}{7+11} \text{ or } \frac{8}{18}$$

the third is greater than the first, but less than the second.

In practice it is convenient to employ fractions having either the same denominators, or which may easily be reduced to others of equal value having the same denominators. The numbers 10, 100, 1000, &c., suggest themselves for this purpose: indeed it may immediately be seen that the ordinary system of decimal numeration may be extended so as to allow of a representation of such fractions. If we consider the number 11111, we see that for every step which we make to the right, we find a unit which is only the tenth part of the preceding unit. Place a point *on*[*] the unit's place (to mark its position), and let the same method of valuation be carried further. Then in 11111·1111, the first 1 after the point should stand for one-tenth of the preceding, or one-tenth of a unit; the second for one-tenth of a tenth, or one-hundredth, and so on. The fundamental theorem of decimal fractions, in this view of the subject, is that which shows, for example, that 12·2345 (defined to mean 1 ten, 2 units, 2 tenths, 3 hundredths, 4 thousandths, and 5 ten-thousandths) is the same as 122345 ten thousandths; or that all the number, such as it would be if the units' column were on the right, may be taken as a numerator, and the denomination of the right hand figure as a denominator. Thus—

$$65{\cdot}483 \text{ or } 60 + 5 + \frac{4}{10} + \frac{8}{100} + \frac{3}{1000}$$

$$\text{is } \frac{60000}{1000} + \frac{5000}{1000} + \frac{400}{1000} + \frac{80}{1000} + \frac{3}{1000}$$

$$\text{or } \frac{65483}{1000}$$

No fraction can be reduced to an equivalent decimal fraction, if its denominator contain any prime factor except 5 or 2 (the divisors of ten). But this is of no consequence in practice, since it may easily be shown that for any fraction can be found a decimal fraction which shall be as near to it as we please. For instance, suppose it required to find a decimal fraction which shall not differ from $\frac{3}{41}$ by so much as the hundred thousandth part of a unit. Then—

$$\frac{3}{41} = \frac{300000}{4100000} = \frac{\frac{300000}{41}}{100000} = \frac{7317\frac{3}{41}}{100000}$$

or 7317 hundred thousandths of a unit differs from $\frac{3}{41}$ by only $\frac{3}{41}$ of the hundred thousandth of a unit, or by less than the hundred thousandth part. It is from such a transformation that the common rule is derived.

It is common to say that a result is true to a certain number of places of decimals when any alteration of any place would make it further from the truth. Thus, the diameter of a circle being unity, the circumference lies between 3·1415 and 3·1416, but nearer to the latter; whence the same circumference, true to four places of decimals, is 3·1416. Similarly, 62·13299, taken true to two places, is 62·13; to three, 62·133; to four, 62·1330. Again, ·625, taken true to two places, might be either ·62, or ·63; but the latter is generally taken. When a decimal fraction cannot be found exactly equal to a given common fraction, the division by which the numerator is found, leads to what is called a CIRCULATING DECIMAL.

For subjects closely connected with the theory of fractions, see RATIO; PROPORTION; INCOMMENSURABLE.

FRACTIONS, CONTINUED. A continued fraction is one which has a fraction in its denominator, which again has a fraction in its denominator, and so on: such as

$$\cfrac{1}{2 + \cfrac{3}{7 + \cfrac{6}{1 + \cfrac{2}{3}}}}$$

A more convenient way of writing such fractions is desirable; in the present article we shall adopt the following:—

$$\frac{1}{2 +}\,\frac{3}{7 +}\,\frac{6}{1 +}\,\frac{2}{3}$$

$$\text{Thus } \cfrac{a}{b + \cfrac{c}{d + \cfrac{e}{f}}} \text{ is written } \frac{a}{b +}\,\frac{c}{d +}\,\frac{e}{f}$$

The use of continued fractions is as follows: by converting a common fraction with a large numerator and denominator, into a continued fraction, we are able to find a succession of more simple fractions which are alternately greater and less than the given fraction, and approach to it with great rapidity. Let $\frac{a}{b}$ be the given fraction, a being less than b; proceed as in the rule for finding the greatest common measure of a and b, and let q, r, s, t, &c., be the quotients obtained in the process; then

$$\frac{a}{b} = \cfrac{1}{q + \cfrac{1}{r + \text{\&c.}}} \qquad \text{or } \frac{1}{q +}\,\frac{1}{r +}\,\frac{1}{s +}\,\frac{1}{t +} \text{ \&c.}$$

---

[*] It will be very useful to the student to remember that this decimal point *belongs to the unit's place*, and is not an introduction *between* the integers and the fractions.

For instance, let the fraction be $\frac{5119}{28319}$

$$\left.\begin{array}{r} 5119)28319(5 \\ \text{Rem. } 2724)5119(1 \\ 2395)2724(1 \end{array}\right\}$$
&c., as in the method of finding the greatest common measure.

The succession of quotients thus obtained is

5, 1, 1, 7, 3, 1, 1, 2, 1, 3, 1, 2;

which are to be used as follows in forming the succession of approximate fractions. The first and second are always

$$\text{1st } \frac{1}{\text{first quotient}} \text{ in this case } \frac{1}{5}$$

$$\text{2nd } \frac{\text{2nd quotient}}{\text{1st qu.} \times \text{2nd qu.} + 1} \text{ . . . . . } \frac{1}{5 \times 1 + 1} \text{ or } \frac{1}{6}$$

To form the succeeding numerators and denominators there is one uniform rule for both, as follows: Multiply the last found term by the first quotient remaining to be used, and add the last but one; as in the following process, where (*) denotes that the incoming quotient is unity, and that the multiplication is therefore unnecessary.

	Numerators.	Denominators.
1st	1	5
2nd	1	6
3rd*	2	11
New quotient	7	7
	14	77
	1	6
4th	15	83
New quotient	3	3
	45	249
	2	11
5th	47*	260*
	15	83
6th	62*	343*
	47	260
7th	109	603
New quotient	2	2
	218	1206
	62	343
8th	280*	1549*
	109	603
9th	389	2152
New quotient	3	3
	1167	6456
	280	1549
10th	1447*	8005*
	389	2152
11th	1836	10157
New quotient	2	2
	3672	20314
	1447	8005
12th	5119	28319

The succession of fractions continually approximating to the given fraction, and ending in it, is then

$$\frac{1}{5}, \frac{1}{6}, \frac{2}{11}, \frac{15}{83}, \frac{47}{260}, \frac{62}{343}, \frac{109}{603}, \frac{280}{1549}, \frac{389}{2152}, \frac{1447}{8005}, \frac{1836}{10157}, \frac{5119}{28319};$$

these approach nearer and nearer to the last, than which they are alternately greater and less; the first greater, the second less, the third greater, and so on; but the second is not so much too small as the first is too great, nor the third so much too great as the second is too small, &c. The error committed by assuming any one of the approximate fractions instead of the final result, is less than a fraction having unity for its numerator, and the product of the denominator in question and the next denominator for its denominator. Thus—

$$\frac{1}{5} \text{ is not wrong by } \frac{1}{5 \times 6} \text{ or } \frac{1}{30}$$

$$\frac{1}{6} \text{ ,, ,, } \frac{1}{6 \times 11} \text{ or } \frac{1}{66}$$

$$\frac{2}{11} \text{ ,, ,, } \frac{1}{11 \times 83} \text{ or } \frac{1}{913}$$

$$\frac{15}{83} \text{ ,, ,, } \frac{1}{83 \times 260} \text{ or } \frac{1}{21580}, \text{ \&c.}$$

If it be desired to verify one of the fractions without proceeding to the end of the process, observe that the numerator of the difference of any two succeeding fractions is unity. Thus—

1 × 6 exceeds 1 × 5 by 1
1 × 11 falls short of 2 × 6 by 1
2 × 83 exceeds 15 × 11 by 1
15 × 260 falls short of 83 × 47 by 1 &c.

No fraction, having a less denominator than one of the approximate fractions, can come so near to the original fraction as the one which is obtained by the process. Thus, $\frac{109}{603}$ is nearer to $\frac{5119}{28319}$ than any possible fraction which has an integer numerator, and an integer denominator less than 603.

FRACTIONS, DECOMPOSITION OF, a method of much use in the integral calculus for reducing products of the form $\mathrm{X}(x-a)^{-m}(x-b)^{-n}$ . . . . . in which X is rational and integral, to the sum of terms of the form $\mathrm{K}(x-a)^{-k}$, in which K is independent of x. But if X be of a higher dimension than $m+n+$ . . . there is also a quotient.

This quotient may be easily found by the short rule for division by $x-a$. To divide $px^m + qx^{m-1} +$ . . . by $x-a$, take the first coefficient, multiply it by a and add the next; repeat this process to the end, taking care to use 0 for the coefficient of any missing term. The results, beginning with the first coefficient, are the coefficients of the quotient, except the last, which is the remainder. Thus in dividing $2x^7-2x^6+x^3+x-1$ by $x-3$, the coefficients are

2 −2 0 0 1 0 1 −1

The results of the rule are

2 4 12 36 109 327 982 2945

Hence the quotient is $2x^6+4x^5+12x^4+36x^3+109x^2+327x+982$, and the remainder is 2945. To divide by $x+a$, or $x-(-a)$, use $-a$ as a multiplier.

Thus to find the quotient of x^8-2x^3+4 divided by $(x-1)^3(x+1)^2(x-5)$, the process is as follows, it being seen beforehand that the answer is of the second degree. We omit all the work which is of no use in the final result.

```
1   0   0
1   1   1
1   2   3
1   3   6
1   2   4
1   1   3
1   6  33
```

When we divide x^8-2x^3+4 by $x-1$ the three first terms of the quotient are $x^7+x^6+x^5$: two divisions more by $x-1$ give $x^5+3x^4-6x^3$. We then divide twice following by $x+1$, still preserving only three terms, and the result is x^3+x^2+3x, and the final division by $x-5$ brings out $x^2+6x+33$ for the three first terms of the final quotient, that is, for the whole quotient. For verification the order of the divisions may be varied.

When all the roots of the denominator are unequal, that is, when the quantity to be reduced is of the form $\mathrm{X}(x-a)^{-1}(x-b)^{-1}(x-c)^{-1}$ . . . . where a, b, c, &c., are all unequal, the process for finding the reduced form of the remainder is very easy. Strike out $(x-a)^{-1}$ and make $x=a$ in the form thus mutilated; let this result be A. Next strike out $(x-b)^{-1}$, and make $x=b$; let the result be B; and so on. Then the fraction $\mathrm{X}(x-a)^{-1}(x-b)^{-1}$ . . . . is the quotient, if any, $+\mathrm{A}(x-a)^{-1}+\mathrm{B}(x-b)^{-1}+$ . . . . Thus to reduce the expression $x^6 \div (x-1)(x-2)(x+1)$, we set down all the work, as follows; the quotient being of the third degree—

$$\begin{array}{cccc} 1 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 \\ 1 & 3 & 7 & 15 \\ 1 & 2 & 5 & 10 \end{array} \qquad \begin{array}{r} 1^6 \div (-1 \times 2) = -\frac{1}{2} \\ 2^6 \div (1 \times 3) = \frac{64}{3} \\ (-1)^6 \div (-2 \times -3) = \frac{1}{6} \end{array}$$

And the final result is

$$\frac{x^6}{(x-1)(x-2)(x+1)} = x^3+2x^2+5x+10$$

$$-\frac{1}{2}\frac{1}{x-1} + \frac{64}{3}\frac{1}{x-2} + \frac{1}{6}\frac{1}{x+1}$$

When the roots of the denominator are not all equal, the way of proceeding which is most easy in the simple cases which generally occur in practice, will be best caught from an example. Suppose, for instance, that $(x^4+1) \div (x-1)^2(x-2)(x+1)$ is the fraction to be reduced. Begin with the denominator $(x-1)(x-2)(x+1)$, and by the preceding rule, obtain the result,

$$\frac{x^4+1}{(x-1)(x-2)(x+1)} = x+2-\frac{1}{x-1}+\frac{17}{3}\frac{1}{x-2}+\frac{1}{3}\frac{1}{x+1}$$

Divide both sides by $(x-1)$, and turn $(x+2)\div(x-1)$ into $1+3\div(x-1)$, and also by the rule, convert

$$(x-1)^{-1}(x-2)^{-1} \text{ into } -(x-1)^{-1}+(x-2)^{-1}$$

$$(x-1)^{-1}(x+1)^{-1} \text{ into } +\frac{1}{2}(x-1)^{-1}-\frac{1}{2}(x+1)^{-1}$$

and the result is

$$\frac{x^4+1}{(x-1)^2(x-2)(x+1)}=1-\frac{15}{6}\frac{1}{x-1}-\frac{1}{(x-1)^2}$$
$$+\frac{17}{3}\frac{1}{x-2}-\frac{1}{6}\frac{1}{x+1}$$

More complicated examples may be seen in the 'Differential Calculus' ('Library of Useful Knowledge'), p. 273. The above will be sufficient for ordinary purposes.

FRACTIONS, VANISHING. This term is applied to fractions in cases where a supposition is made which destroys both numerator and denominator at the same time. Thus:

$$\frac{x^2-1}{x-1} \qquad \frac{\text{log. } x}{x-1}, \qquad \frac{a^x-a}{b^x-b},$$

are fractions which all assume the form $\frac{0}{0}$, when $x=1$; that is, though for any other value of x they represent operations of ordinary arithmetic, yet in the particular supposition that x is unity, they all end in a direction to find out how many times *nothing* is contained in *nothing*. The first answer to this seems to be that the fraction may, in such a case, have any value we choose to assign, for nothing taken once, or twice, or thrice, &c., is still nothing: that is to say, according to the rules of common algebra, since $0=0\times a$, whatever a may be, it follows that 0 divided by 0 may be a. But this is carrying operations which are defined with regard to magnitudes further than is contemplated in their definition, and applying them to a symbol which simply represents the absence of all magnitude. Such a process may then be rejected without scruple.

But this question remains: granting that the preceding reasoning does not entitle us to give the preceding fractions any value we please, can they be said to have a value at all when $x=1$? To settle this point in part, we must ask not what the preceding fractions are when x is unity, but what becomes of their value when x is made to approach nearer and nearer to unity. To take the first as an instance, we find that

$$\frac{x^2-1}{x-1}=x+1 \text{ for all } \textit{values} \text{ of } x.$$

Consequently—I. Whenever x is greater than 1, the fraction is greater than 2. II. As x approaches to 1, the fraction approaches to 2. III. The fraction may be made as near to 2 as we please by making x sufficiently near to unity. Hence it follows that if when $x=1$, the fraction have a value at all, that value must be 2. Similarly it may be proved of the second and third fractions, that if they *have* values when $x=1$, these values must be 1 and $\frac{a \log a}{b \log b}$.

Much discussion has arisen as to whether vanishing fractions have values or not, as if such a question could be one of deduction from the ordinary reasonings with regard to magnitude. The truth is, that any one may either assert that such fractions have values, or may altogether refuse to consider them, according to his ideas of convenience or propriety. Nobody doubts that if the answer to a problem were

$$\text{'}y=\text{the value of } \frac{\log x}{x-1} \text{ when } x=1,\text{'}$$

one of two courses must be taken: either the value of y must be declared to be unity, or else the evanescent form of the fraction must be recognised as arising from a misconception of the problem, by which factors of the form $x-1$ (where $x=1$) have been used under the idea that they were of the form $x-1$ (where x is not $=1$): the problem must then be reconsidered, and the (so called) mistake corrected. But the correction will always lead to the result $y=1$, and those who employ the second method in preference to the first will not deny that they knew as much when they first saw their (so called) erroneous result.

It is not worth while to discuss the particular arguments used with respect to the isolated question of vanishing fractions, since the difficulty raised with regard to them belongs to a class of questions so extensive that they might form the subject of a separate science. Under the heads NOTHING, INFINITY, LIMITS (THEORY OF), &c., will be found those considerations which apply to all the cases.

The method of finding the value (or correction, if the reader please) of a vanishing fraction whose numerator and denominator disappear when $x=a$, is to make a new fraction with the differential coefficients of that numerator and denominator, and then to substitute a for x. If the result be still a vanishing fraction, repeat the process with new differentiations, and so on. Thus, to find the value of the third fraction above mentioned,—

$$\text{diff. co. of } a^x-a \text{ is } a^x \log a$$
$$\text{diff. co. of } b^x-b \text{ is } b^x \log b$$
$$\frac{x^x \log a}{x^x \log b}, \text{ when } x=1, \text{ is } \frac{a \log a}{b \log b}.$$

FRACTURE. Injuries complicated with the breaking of a bone are called fractures.

The comparative importance of such accidents depends in the first place upon that of the bone which is broken. The most dangerous fractures in this point of view are those of the vertebræ and skull, which inclose organs immediately essential to life, and extremely susceptible of injury. The *processes*, or projecting parts, of the vertebræ are sometimes broken without very serious consequences; but if any of the rings of bone which encompass the spinal cord be thus injured, death almost certainly ensues, and the danger is imminent in proportion to the nearness of the injured vertebra to the head. If the fracture take place above the fourth vertebra of the neck, reckoning downwards, death is generally instantaneous from paralysis of the nerves of respiration. Fracture of the *basis* or floor of the skull is often instantly fatal, for analogous reasons. The *sternum*, or breastbone, and ribs, cover parts not so immediately essential to life, and, for many reasons, not so liable to suffer from violence done to their external defences as those to which we have already adverted. Fracture of the sternum can scarcely happen without the direct application of considerable force; and for that reason is both serious and rare. The ribs, on the contrary, are more easily and frequently broken than any other bones; and generally speaking the consequences are not at all serious, if proper measures be adopted. The fracture unites readily; and the chief danger to be apprehended is inflammation of the serous membrane called the *pleura*, which lines the cavity of the chest, or of the lung. [PLEURISY; PNEUMONIA.] This danger is of course increased if the lung be wounded by the splintered ends of the bone, which is sometimes the case, especially when the fracture is the result of direct force. The bones of the pelvis are seldom broken, for the same reason that determines the rare occurrence of fracture of the sternum; but the accident is generally serious, and not unfrequently fatal, from injury to the bladder and other important organs included in the pelvic cavity, or connected with the bones which circumscribe it. Fractures of the bones of the face, though distressing and painful at the time, generally do well; and are of consequence chiefly on account of the disfigurement they sometimes occasion.

The limbs are so essential to the purposes of life, and their usefulness depends so much upon the preservation of the shape of their numerous bones, upon the integrity of their joints, and upon the free and separate mobility of their muscles and tendons, that anything calculated to injure them permanently in these particulars is a matter of serious importance. Hence the great interest that has always been attached to fractures occurring about these parts; none of which can be considered as slight accidents, for in various degrees they all threaten the future usefulness of the limb.

We feel that the subject of fracture, particularly of the limbs, is one that hardly admits of compression within moderate limits; and are aware that in attempting to compress it we must sacrifice order, if not perspicuity, to brevity. Our principal object, however, will be to give a clear explanation of certain technical terms, by which important varieties of these injuries are distinguished; and which, though frequently made use of in conversation and in the course of judicial proceedings, are often misapplied or imperfectly understood: with this we shall interweave as much general information as possible, subjoining what may be necessary to complete an outline of the whole subject.

It can hardly be necessary to explain what is meant by *transverse* and *oblique* fracture: we may observe, however, that the distinction is practically of great consequence. In the first, or *transverse* variety, the bluntness of the ends of the broken bone in some measure preserves the contiguous soft parts from laceration at the time of the accident; it also opposes a considerable obstacle to the displacement which arises afterwards from muscular contraction; but it chiefly conduces both to the diminution of present suffering and to the prosperous event of the case, by facilitating the speedy and perfect restoration of the displaced bone to its proper situation, and its steady retention, when restored, by mechanical means.

On the other hand, as most of the bones liable to fracture are cylindrical, or present flattened surfaces meeting in as many solid angles, if they be broken obliquely, the ends of the bone will be sharp-edged or pointed: hence they are generally separated from each other to a much greater extent than is usual in transverse fracture, and there is not only much more suffering from the laceration of sensitive parts and from portions of them being included and pressed between the broken surfaces, but great difficulty is often experienced in disentangling the ends of the bone, and bringing them into close apposition; and still more in retaining them, from their tendency to slip past each other during the spasmodic and powerful contractions of the wounded and irritated muscles. The result of such fractures is often unsatisfactory, in spite of the utmost care and skill; and some distortion and shortening of the limb is inevitable in severe cases.

Comminuted Fracture.—When a bone is crushed, or fissured in more than one direction, so that portions of it are detached from the rest, the fracture is said to comminuted. From the facility generally experienced in replacing the bone, or at least in straightening and supporting the limb in these cases, they often end better than apparently less serious oblique fractures. Perhaps one reason may be that the direct application of force, by which they are generally produced, has some effect in stunning the muscles and deadening the injurious influence of their contraction. If there be much contusion of the soft parts, considerable inflammation and fever may supervene, and the recovery will be tedious in proportion; but the eventual restoration of the natural shape and length of the limb is frequently more complete than might be expected.

Fracture extending into a joint.—A bone may of course be broken in the situation of a joint; or, if the fracture occur at some distance, a fissure may extend longitudinally into one of these cavities. This circumstance is a very important aggravation of the injury. The synovial membranes which line the joints are peculiarly impatient of irritation, and when they become inflamed, the constitutional disturbance is often considerable, and the attendant, or, as it is called, the *symptomatic* fever, is of a very acute type. When the larger joints, such as the knee, are concerned in injuries of this kind, the old surgeons frequently recommended amputation of the limb. Modern experience has shown that this may generally be dispensed with; but the greatest skill and watchfulness are required and often baffled in endeavouring to prevent the occurrence of a stiff joint (*anchylosis*), and to keep the limb in the most useful position, if it should occur; a position which is not always the most conducive to the case, or indeed to the recovery, of the patient, and therefore not always eligible.

Fracture complicated with dislocation.—If a bone be dislocated as well as broken, it may be difficult or impossible to carry into effect the measures which are necessary for the satisfactory treatment of either injury, and the result is permanent distortion and crippling of the limb. This is of course an extreme case, and is not likely to happen unless the fracture take place very near the dislocated joint, so that a firm hold cannot be taken of the detached end of the bone. If, however, the fissure in the bone does not extend to the joint, the constitution does not, upon the whole, suffer so materially as might be expected in consequence of the double injury, except in particular cases, such as those complicated with traumatic delirium, on which, as the subject is curious, we shall here take occasion to say a few words.

Traumatic delirium (*τραῦμα, a wound*).—This affection is by no means confined to fractures with dislocation, or to injuries of which fracture forms a part. It appears however to be more frequently a consequence of injuries of this nature than of others, and particularly of the fracture of the fibula immediately above the ancle, which is often followed by dislocation of the foot. [Fibula, in Nat. Hist. Div.] The patient rambles in his ideas, is generally very talkative, and in a state of great alarm and apprehension, expecting, for instance, to be led to execution for some fancied crime. He is commonly pale and cold, free from fever, and quite unconscious of pain. If not prevented, he will rise from his bed and move about the room, using his shattered limb with perfect unconcern. Traumatic delirium has some points of resemblance with delirium tremens, and like it, occurs for the most part in over-stimulated and exhausted constitutions. It is sometimes fatal, but may generally be relieved by large quantities of wine and opium.

Compound fracture.—If the injury of which we are treating be confined to the bones and the parts immediately around them, the fracture is said to be *simple*; but if the bone be protruded through the skin, or an external wound otherwise inflicted communicate with the interval between the broken surfaces, the fracture is said to be *compound*. However small the wound in the skin may be,—unless it can be brought to heal by the first intention, which, though it rarely succeeds, should be always attempted,—this is by far the most serious aggravation of the injury, whether we regard the suffering of the patient, the progress of the case, or the prospect of recovery. A simple fracture, however extensive, if not into a joint, may generally be expected with confidence to be well enough to permit the accustomed use of the limb in a period ranging from two to eight weeks; the pain and constitutional derangement seldom lasting beyond a few days. But a compound fracture threatens life, and, speaking generally, is at best an affair of many months of suffering and sickness. This remarkable difference originates in the wide constitutional sympathies of the skin as an organ of sensation and secretion; in the importance of its function as a covering for the subjacent parts; and in its great proneness to become inflamed when the subject of a punctured and lacerated wound. It further results from the tendency of the inflammation to propagate itself from the edge of the skin along the track of the wound to the periosteum and other deep-seated parts; it commonly spreads very extensively in cellular tissue between the muscles, under the aponeurotic expansions which invest and separate them, and within the synovial sheaths of their tendons. Some degree of inflammation among these parts takes place in simple fractures, but it seldom exceeds manageable limits and the lower degrees of it may perhaps be considered as curative. But the inflammation which follows a compound fracture puts a stop to all the natural processes of restoration, and renders the artificial means, in other cases usefully employed to promote them, ineffectual or inapplicable. It is attended with incessant and exhausting fever, at first ardent and afterwards irritative and hectic [Fever], and occasions deep-seated abscesses, extensive destruction of the soft parts (*sloughing*), and tedious separation of dead bone (*exfoliation*). Such are some of the disastrous consequences of a compound fracture, an accident which, in its severer forms, presents such a scene of suffering and a succession of such formidable drains upon the strength, that, on the balance of evils, amputation is often a preferable alternative.

Diagnosis of fracture.—Much need not be said of the means by which the existence of a supposed fracture may be ascertained. The nature of the accident is generally obvious enough, and the less the parts are handled the better; but where there is any doubt, it may be removed by attending to the grating sound, or the sensation communicated to the touch occasioned by slightly moving the broken ends of the bone against each other. This symptom is called *crepitation*.

Treatment.—The principles of treatment are, in the first place, to soothe by all possible and prudent means the muscular irritation and spasm which are the immediate and most urgent consequences of a recent fracture. The patient is to be placed in the easiest posture, which, if the thigh or leg be broken, is generally on the same side or on the back; the limb is to be supported on soft pillows, the contiguous joints being half-bent in order to favour as much as possible the relaxation of each class of muscles, especially the flexors; gentle friction, warm fomentations, or cold evaporating lotions are to be used according to the circumstances of the case and the feelings of the patient.

When the relaxing rigidity of the muscle will permit, which may not be for some hours or days, the bone is to be restored as nearly as possible to its proper situation by the gentle application of force in any required direction. Violence would defeat its own object by reproducing spasm. One hand or an assistant should steady the upper portion of the limb while the lower portion is drawn down and turned till the proper length and bearings are restored. This process, which is called the *reduction* or *setting* of the fracture, cannot always be completed on the first attempt; and it is sometimes advisable, and indeed only possible, to effect it by degrees. The displacement may also return; and in oblique fracture this will certainly happen unless the case admits of a very fortunate adjustment of the bandages. The process we have described must then of course be repeated as often as circumstances may render it necessary. The setting of a broken limb is not, as people generally imagine, a piece of legerdemain, to be effected in a moment by some wonderful exertion of dexterity, and then to be announced in oracular phrase by the surgeon as if it were something too mysterious for a plain man to understand. It is a perfectly simple and straightforward measure; and little more than common sense and a gentle hand are necessary for its proper execution if it be possible to effect it at all.

When the limb is reduced, it is to be placed in *splints*, which are thin pieces of wood or other material of the requisite firmness and length, and suitably shaped and hollowed out to fit evenly without making undue pressure upon prominent points, such as the ankle. The skin is to be protected by folds of linen or thin soft pads a little wider than the splints, which are also useful to prevent them from slipping. When everything is properly arranged as to position, the splints are to be bound upon the limb with a moderate degree of pressure; and it is right to remove and re-adjust them occasionally, in order to detect and rectify any deviation from the correct line of the bone that may arise or become apparent as the swelling subsides.

Where there is no fear of the bone being displaced by the action of the muscles that are attached to it, or by the restlessness of the patient, it is not necessary to apply splints, which are only useful in preventing motion, and otherwise rather retard the progress of the case by their pressure, and for other reasons.

In fracture of the ribs, it is sufficient to apply a broad belt or bandage to prevent them from alternate depression and elevation in the act of breathing, which can be carried on sufficiently well by the diaphragm alone [Respiration, in Nat. Hist. Div.]; and all such means are inapplicable in many cases, such as fracture of the vertebræ, and of the neck of the thigh-bone, where all that can be done of a mechanical kind is to place and keep the patient in a proper position. This can be done most effectually by the help of a bedstead invented by Mr. Earle, the frame of which is jointed, so that the back may be raised to any required inclination, the knees being also raised, and the feet, if necessary, bound to a cross-board. The mattrass is provided with moveable pieces, which preclude the necessity of change of position for any purpose. The paramount importance of constitutional treatment and a strict regulation of the diet need scarcely be adverted to in this as in all cases of injury, in which a primary object is to repress or prevent inflammation.

Union of fractured Bone.—The process by which fractured bones are united is generally uninterrupted in simple cases, if the constitution be good and the accompanying contusion not very considerable. The extravasated blood is soon absorbed, and the swelling and inflammation subside. The interior lacerations heal, and the soft parts round the ends of the fracture become consolidated with the periosteum, or fibrous investment of the bone, which swells and unites at the torn edge. In this consolidated mass, which forms a soft case for the bone for some distance above and below the fracture, but is thickest just at that point, particles and spicula of bone are gradually deposited, till at length it becomes rigid and firm, holding the ends of the bone in close contact and peventing them from slipping away from each other, like the slider of a parasol. At length the patient finds the strength of his limb restored, and conscious of the change, can no longer be persuaded to refrain from using it. After a certain period, which has been differently stated—it may be six or seven months in the case of a large bone—the fractured ends become firmly adherent by the deposit of bony matter between them; the exterior case becomes absorbed, and the cure is complete, the bone being rather thicker and generally somewhat stronger and more solid in the situation of the fracture than before the accident. The whole of this process is much quicker in infants and children than in adults, and somewhat more slow in advanced periods of life than in the middle age. Taking all ages, it ranges, as we have said, from two to eight or ten weeks—speaking, of course, of the period at which the limb becomes firm enough to perform its functions.

The treatment and progress of compound fracture depend upon the circumstances of each case; and it would lead us too far to enter upon them. The principles of management, however, are the same, as are likewise, in the main, the natural processes by which firm union is established.

Ununited Fracture.—It sometimes happens that, without any assignable cause, the processes we have just spoken of do not go forward; and the fracture, originally perhaps a very simple and promising one, either does not unite at all, or unites only by a tough and flexible substance like ligament or tendon; and this even where nothing faulty can be discovered in the constitution of the patient, or in the management of the surgeon. Attempts are made to excite irritation and promote the deposition of bony matter in this new substance by rubbing the ends of the bone together, and in other ways. Such attempts not unfrequently fail, and the bone remains flexible and useless for life.

Causes of Fracture.—We have said nothing of the various ways in which fractures may accidentally take place, because each reader can imagine them for himself. There are, however, some circumstances with reference to this subject which it is proper to mention. In the first place, the simple action of the muscles, without any blow or external pressure, is sufficient to break the bones. Such is, generally speaking, the case in transverse fractures of the *patella* or knee-pan, and occasionally in those of the *olecranon*, or point of the elbow. When these are broken off by a sudden jerk of the muscles attached to them, the detached portion of bone is carried up to some distance, and can rarely be brought into sufficiently close apposition to unite by bony matter. But the ligamentous substance we have mentioned in speaking of ununited fracture is formed between the broken surfaces; and if proper care be taken not to permit it to be stretched while it is yet soft and extensible, it answers every purpose in these cases nearly as well as bone. When one patella has been broken in this way, the other is almost sure to follow soon after, having a double duty to perform in supporting the muscular contraction by means of which the thigh is brought to a straight line with the leg in the erect posture.

Imperfect Fracture.—There are some conditions which modify the liability to the occurrence of fractures. Among these may be mentioned the soft and cartilaginous state of the bones in young infants before the earthy matter has been completely deposited. At this period it is not uncommon to find that although the limb is flexible at a certain point, no crepitation can be felt, and that in point of fact there is no actual separation of the ends of the bone. This is called *imperfect* fracture.

The opposite state of brittleness prevails in old age; and owing to this circumstance, a very slight accident will often cause a fracture of the neck of the thigh bone, the soft parts commonly receiving little injury. In these instances ligamentous union is all that can be effected, and the limb remains for the remainder of life to a great degree crippled.

Fragilitas Ossium.—A still more brittle condition of the bones is sometimes co-existent with cancer, and probably other morbid states of the constitution. It is called *fragilitas ossium* (fragility of the bones), and sometimes reaches a remarkable pitch. A late eminent physician informed the writer that, being called to attend upon a lady in her pew at church, he found that she had broken her thigh in rising from her hassock; and in attempting to raise her, he broke her arms. There is generally little injury of the soft parts in these fractures, and they are said to unite rather more quickly than others.

Some persons have asserted that the bones are more brittle in winter than in summer; but it does not require an hypothesis so improbable as this to explain the principal fact on which the proof has been rested, namely, the more frequent occurrence of fractures in frosty weather.

FRAISE is a row of palisades placed in a horizontal or oblique position on the exterior, or on the edge of the ditch, in order to increase the difficulty of passing over it at the time of an assault.

FRAMBÆSIA. [Skin, Diseases of.]

FRANCHISE, a species of incorporeal hereditament. Franchise and liberty are used as synonymous terms, and their definition is a royal privilege, or branch of the prerogative, subsisting in the hands of a subject. Such privileges must arise, therefore, from the grant of the crown, though in some cases they may be held by prescription, which presupposes a grant. The kinds of them are various, and almost infinite, and may subsist in corporations, in one man, or in many, as co-tenants. Thus a county palatine is a franchise, and so are privileges given to corporate bodies, forests, chases, the right to wreck, estrays, &c. Franchises may be lost or forfeited by the parties who enjoy them, if they misuse their privilege or neglect to perform the requisite duties in respect of them [Ferry]; and if the owners are disturbed or incommoded in the proper exercise of their franchise, which is an injury known to the law as a disturbance of franchise, they may have remedy in an action, or where the franchise is to levy a toll, they may distrain for the amount alleged to be due.

FRANCISCANS. In the Biographical Division an account of the chief order is given under Francis, St.; and it is there stated that even of these there was considerable diversity in the practice of the rules of the order. One part, called Spirituals, contended for the observance of the rules in all their strictness; the others, called Conventuals, advocated the possession of property to any extent by the body as a community, though still professing poverty as individuals. The Popes were partisans now of one branch and now of the other, during the 15th and 16th centuries; and various ineffectual attempts were made to efface the differences. The Fratricelli [Fratricelli] entirely separated from them in the 15th century, or rather founded a new order, adopting the primitive rules of St. Francis. As early as 1294 a number separated themselves, and formed a sub-order called Celestin Hermits, or Minorites; but this order was suppressed early in the 14th century by the efforts of the Inquisition. In 1302 the Clare Brethren also formed a separate sect, who, after some time took the name of Observantins. To this order belonged the nuns of St. Clare (as they were erroneously called, for the name was derived from a river in Spain, where the first establishment was formed), or Minoresses, whose nunnery was in London, near Tower Hill. In 1525 a new secession ended in the establishment by Pope Clement VII. in 1528 of the order of *Capuchins*, so called from the pointed cowl or capuche which they added to the ordinary Franciscan habit. The Capuchins professed an abstinence from all worldly pleasures, and by their humility, gravity, and attention to their duties, ultimately acquired great popularity and influence, though they had to struggle for a long time against the power and influence of the Franciscans for their very existence. In 1619 they acquired the right of electing their own general, who held office for three years. Nuns of this order were first instituted at Naples in 1583. During the early part of the present century the order was suppressed, and the possessions secularised, in all the Roman Catholic countries of Europe, except Portugal, Spain, and Sicily; but since 1814, settlements of the order have been made in Italy, Germany, and other places. Another sect was formed in 1532, by the authority of the Pope, called Reformed Franciscans in Italy, Recollets in France, and Barefooted Franciscans in Spain. They were also known as Friars Minors of the Strict Observance, from their rigid adherence to the original rules of the order. Other orders of less note were the Brothers of the Sack, and the Bridgetine Nuns.

FRANKALMOIGNE. This tenure is thus described by Littleton (§ 133): "Tenant in Frankalmoigne is when an abbot or prior, or other man of religion, or of holy church, holdeth of his lord in Frankalmoigne; that is to say, in Latine, *in liberam eleemosinam*, that is, in free almes. And such tenure beganne first in old time." From this it appears that lands which are held by religious bodies or by a man of religion, are held by this tenure; but neither fealty nor any other temporal service is due. The spiritual services which were due before the Reformation are thus described by Littleton (§ 135): "And they which hold in frankalmoigne are bound of right before God to make orisons, prayers, masses, and other divine services for the souls of their grantor or feoffer, and for the souls of their heires which are dead, and for the prosperity and good life and health of their heires which are alive. And therefore they shall do no fealty to their lord; because this divine service is better for them before God than any doing of fealty; and also because these words (frankalmoigne) exclude the lord to have any earthly or temporal service, but to have only divine and spiritual service to be done for him."

On this section Coke remarks: "Since Littleton wrote, the liturgie or Book of Common Praier of celebrating divine service is altered. This alteration notwithstanding, yet the tenure in frankalmoigne remaineth; and such prayers and divine service shall be said and celebrated as now is authorised; yea, though the tenure be in particular, as Littleton hereafter (§ 137) saith, namely, to sing a mass, &c., or to a *placebo et dirige*, yet if the tenant saith the prayers now authorised, it sufficeth. And as Littleton hath said before (§ 119), in the case of socage, the changing of one kind of temporall services into other temporal services altereth neither the name nor the effect of the tenure; so the changing of spiritual services into other spiritual services altereth neither the name nor the effect of the tenure. And albeit the tenure in frankalmoigne is now reduced to a certaintie contained in the book of Common Prayer, yet seeing the original tenure was in frankalmoigne, and the change is by general consent by authority of parliament, whereunto every man is party, the tenure remains as it was before."

The statute 12 Charles II., which abolished military tenures, expressly excepts tenures in frankalmoigne.

Those who hold lands in frankalmoigne must do the services for which these lands were given. These services are now determined, as Coke says, by the book of Common Prayer. The mode of compelling these tenants to do their duty is thus described by Littleton (§ 136) "And if they which hold their tenements in frankalmoigne will not, or fail to do such divine service (as is said), the lord may not distrain them for not doing this, &c., because it is not put to certainty what services they ought to do. But the lord may complain of this to their ordinary or visitor, praying him that he will lay some punishment and correction for this, and also provide that such negligence be no more done, &c. And the ordinary or visitor of right ought to do this," &c.

Since the statute of 18 Ed. I., called *Quia Emptores*, from the introductory words, there can be no gift in frankalmoigne except by the crown. This tenure, however, as Blackstone observes, "is the tenure by which almost all the ancient monasteries and religious houses held their lands; and by which the parochial clergy and very many ecclesiastical and eleemosynary foundations hold them at this day, the nature of the service being upon the Reformation altered, and made conformable to the purer doctrine of the Church of England."

FRANKINCENSE, Common, obtained from *Abies excelsa* (Dec.), the *Pinus abies* of Linn., consists of two kinds of resin mixed with oil of turpentine. By melting it in water, and straining it through strong cloths, it is deprived of much of its oil, when it is termed pix arida, or Burgundy pitch, and also white resin.

It is scarcely now used internally, but is irritant and diuretic. Externally it is rubefacient, and consequently enters into the composition of many plasters.

FRANKLIN. In the reign of Elizabeth a franklin was a freeholder, or yeoman, a man above a vassal or villain, but not a gentleman. He is mentioned as of this description in several passages of Shakspere's plays. In earlier times he was a personage of much more dignity, and seems to have been distinguished from a common freeholder by the greatness of his possessions. Chaucer's franklin (Introduction to 'Canterbury Tales') was a rich and luxurious gentleman, a chief man at the sessions, and had been sheriff, and frequently knight of the shire.

Fortescue, 'De Legibus Angliæ,' c. 29, describes the franklin as "Pater familias—magnis ditatus possessionibus."

FRANKPLEDGE. [Leet.]

FRATRICELLI, or Little Brethren, (an Italian translation of Fratres minores, or Friars Minors as the Franciscans called themselves) also called *Fratres de paupere vitâ*, a religious sect which arose in Italy towards the end of the thirteenth century. They were Franciscan monks who separated themselves from the grand community of St. Francis with the intention of obeying the laws of their founder in a more rigorous manner than they were observed by the other Franciscans. They accordingly renounced every kind of property, both common and individual, and begged from door to door their daily subsistence, alleging that neither Christ nor his Apostles had any possessions, either individual or in common; and that these were the models which St. Francis had commanded them to imitate. They went about clothed in rags declaiming against the vices of the pope and the bishops, thus preparing the way for the Reformation, and foretold the purification of the church and the restoration of the true gospel of Christ by the real followers of St. Francis. As the Franciscan order acknowledges for its companions a set of men who observe the third rule prescribed by St. Francis, and were therefore commonly called Tertiarii; the order of the Fratricelli had a great number of Tertiarii attached to their cause. These tertiarii, or half monks, were called in Italy *Bizochi* or *Bocasoi*, in France *Beguins*, in Germany *Begwards* or *Beghards*. The Tertiarii differed from the Fratricelli, not in their opinions, but only in their manner of living. The Fratricelli were real monks, subject to the rule of St. Francis, whilst the Bizochi or Beghards, as well as the Franciscan Tertiarii, excepting their dirty habit and certain maxims and observances which they followed in compliance with the rules of their patron saint, lived after the manner of other men, and were therefore considered as laymen; but the denomination was ultimately applied to a great number of other orders and sects, whose followers, female as well as male, pursued a somewhat similar course of life. None of these, however, must be confounded with the true Franciscan Beguines who grew into importance about the same time, but whose origin dates from the 11th century, and whose docrines gave rise to the Lollards. The Beghards were divided into two classes, the *perfect* and the *imperfect*. The first lived on alms, abstained from marriage, and had no fixed dwellings; the second had houses, wives, and possessions, and were engaged in the common avocations of life like other people. Pope Celestin V. was favourably disposed to the Fratricelli, and permitted them to constitute themselves into a separate order. They were submissive to that pope, but they violently opposed his successor, Boniface VIII., and subsequent popes who persecuted their sect. The Fratricelli were accused of great enormities in the beginning of the 14th century, and persecuted by the court of Rome, but they found protection from princes, nobles, and towns, who respected them on account of the austerity of their devotion. In 1317 Pope John XXII. ordered their abolition by a bull, and on their refusal to submit, they were declared heretics. The Fratricelli did not always submit with the meekness of the first Christian martyrs to their persecutors, but frequently opposed force to force, and even put to death some inquisitors in Italy. This sect continued during the 14th century, and spread as far as Bohemia, Silesia, and Poland. The members of it were most severely persecuted in the 15th century, and many of them fled from France to England and Ireland. All the persecutions directed against the sect did not however extinguish it, and some remnants of it existed till the reformation of Luther, whose doctrines they embraced.

FRAUDS, STATUTE OF. [Statute of Frauds.]

FRAUDULENT CONVEYANCE. [Consideration.]

FRAXININ. [Mannite.]

FREE BENCH is the widow's share of her husband's copyhold lands, according to the custom of the particular manor of which the lands are holden. [Copyhold.] As dower is not an incident to copyhold tenure the quantity and duration of the widow's interest are regulated by the custom; it is generally a third for her life, but in some manors it is a fourth part, and sometimes only a portion of the rent. By other customs she takes the whole for her life, and in the manor of Taunton Deane, in Somersetshire, the wife takes the inheritance. In some manors the widow has only a right to Free Bench out of the lands of which her husband died seised; in others, her right attaches upon all the lands held of the manor of which he was seised during the coverture. Frequently her estate is during widowhood only, and sometimes during chaste widowhood. In the manors of East and West Enborne in Berkshire, and Torre in Devonshire, and in some other parts of the West of England, there is the ludicrous custom that where a widow has forfeited her Free Bench for incontinency, if she will come into court riding backwards on a black ram with his tail in her hand, and repeating certain verses more significant than decent, ending with "Therefore pray, Mr. Steward, let me have my land again," the steward is bound to re-admit her to her Free Bench. (Cowel's 'Interp.'; Scriven 'on Copyholds.')

FREE CHURCH OF SCOTLAND, the name adopted by a large body of clergy and laity who seceded from the Church of Scotland in 1843. The history of this secession is as follows. It was part of the policy of the Harley ministry, in Queen Anne's reign, to encourage the Episcopal party and the landed gentry of Scotland, and to depress the Presbyterian. In 1712 they accordingly passed an act (10 Anne, c. 12) restoring to its full vigour the right of lay patronage, which had been virtually abolished in 1690. The church became thenceforward divided into two parties, the supporters of patronage, or the "Moderates," and the anti-patronage men, or, as they were more lately termed, "Non-intrusionists." In 1834 the latter party obtained the majority in the General Assembly, and on the 31st of May of that year the Assembly passed an "Overture and Interim Act on Calls," a measure generally known by the name of the "Veto Act."

To understand the character of this measure, it is necessary to keep in view the method of collating a qualified person to a benefice in Scotland. The licensing of a clergyman, and his ordination and induction to a benefice, are distinct acts. Many clergymen are licensed to preach who never obtain benefices, and in this position they are called "probationers." When a licentiate receives a presentation to a benefice, he presents it, along with an acceptance, to the presbytery within the bounds of which it lies, and they pronounce a sentence sustaining the presentation, and appointing such formalities as the laws of the church sanction, before the presentee is finally ordained and inducted to the benefice. The object of the Veto Act was to make it a law of the church that no presentee was to be held fit to be ordained as minister of a parish unless he were acceptable to the majority of the parishioners. Accordingly, by the Veto Act and other rules for carrying out its principles, presbyteries were directed, when a presentee laid his presentation before them, to appoint him to preach twice in the church, and also to appoint a day for "moderating in a call," or receiving dissents. If a majority of the male heads of families in the parish in communion with the church dissented, the presentee was to be rejected as an unfit person. There was no doubt that it was within the power of the General Assembly to settle what qualifications should be required, in the way of education, character, &c., of every presentee; but the question came to be, whether the church was entitled to require such an external test as the acceptability to the parishioners, and thus virtually counteract an act of parliament under which important civil rights were held.

On the 14th of September, 1834, Lord Kinnoul, patron of the parish of Auchterarder in Perthshire, issued a presentation to that parish in favour of Mr. Young. The presbytery applied the Veto Act to this presentation, and it was found that in a roll of 330 male heads of families, 287 dissented and objected to the presentee's ordination. The presbytery accordingly rejected the presentee. An appeal against these proceedings was taken to the immediately superior ecclesiastical court, the Synod, and thence to the General Assembly, but the acts of the presbytery were confirmed in both these courts. The next step was to call in question the proceedings of these ecclesiastical tribunals in the civil courts. Accordingly an action of declarator was raised in the Court of Session by the patron and the presentee, and on the 5th of March, 1838, the court, by a majority of eight to five, found that the presbytery, in rejecting the presentee on the sole ground that the male heads of families in communion with the church had dissented without assigning reasons, had acted to the hurt and prejudice of the pursuers, illegally, in violation of their duty, and contrary to statute. On the 3rd of May, 1839, this decision was affirmed on appeal in the House of Lords. Mr. Young afterwards raised an action of damages against the presbytery, on the ground of his having been a sufferer by their illegal conduct, and obtained a verdict in his favour. This was called "the Auchterarder case." The presbytery had refused to retrace their steps, and had inducted another person before preventive legal measures could be taken in the matter. But the Lethendy case took a different shape. In 1835 Mr. Clark received a presentation to that parish from the crown, in which the patronage was vested. A majority having dissented, he was rejected by the presbytery. In the mean time the crown, yielding to these proceedings as legal, issued a presentation to another person; and thus the two presentees were able to fight the battle of the legality as a question of patrimonial right. Mr. Clark not only brought an action into court, as had been done in the Auchterarder case, but he likewise applied for an interdict, the counterpart of what is in England called an injunction, and the Court of Session accordingly interdicted the second presentee from presenting himself, and the presbytery from inducting him. The presbytery applied to the General Assembly for instructions, and the Assembly directed them to disregard the interdict of the Court of Session, and to put in force the Veto Act. They therefore proceeded with the induction of the second presentee. On this the majority of the presbytery were cited to appear before the Court of Session, to answer to a complaint for breach of interdict; and on the 14 June, 1839, they were reprimanded at the bar of the court, and informed that a repetition of the offence would be followed by imprisonment.

The celebrated Strathbogie case assumed an aspect considerably different. In June, 1837, Mr. Edwards received a presentation to the parish of Marnoch, which he laid before the presbytery of Strathbogie, the majority of whom were opponents of the Veto Act. A majority of the communicants having vetoed Mr. Edwards, the presbytery, by the direction of the superior church courts, rejected him. A second presentation to a different person was granted by the patron, but Mr. Edwards, as in the case of Lethendy, obtained an interdict against the presbytery taking any steps in favour of the second presentee, and raised an action to have it declared that his own rejection was illegal. In these circumstances the presbytery resolved to postpone their proceedings until the courts of law had given final judgment. Mr. Edwards obtained a decree to the effect that the refusal of the presbytery to take him on trial and induct him was to his hurt and prejudice, illegal, in violation of duty, &c., and enjoining them to take him on trial, and act as if no law of the church such as the Veto Act existed. The presbytery applied to the superior church courts, which directed them still to put the Veto Act in force. Thus, being directed by the courts of law to take a particular step, and by the superior ecclesiastical judicatories to take one in the reverse direction, the presbytery would of course act as their own views of a proper jurisdiction in the matter might direct. The majority being of the moderate party, they decided by a majority that they would obey the courts of law, and they consequently took Mr. Edwards on trial, and inducted him. Then occurred an event from which every one saw that the Church of Scotland must inevitably be split in two. On the 13th December, 1839, the commission of the General Assembly suspended the majority of the presbytery of Strathbogie from their ecclesiastical functions, directed other clergymen to perform their duties, and declared the minority of the presbytery to be entitled to perform the corporate functions of the presbytery. On the 27th May, 1841, this suspension was made perpetual by the General Assembly deposing the members of the majority of the presbytery, and recalling Mr. Edwards's licence as a preacher. In the meantime the court of session interdicted the practical application of these proceedings of the ecclesiastical courts, directing the interdicts against any clergymen of the established church usurping the functions of the majority of the presbytery of Strathbogie, whether individually or collectively. The execution of the sentence of deposition by the General Assembly was also interdicted. Thus the presbytery of Strathbogie was divided into two bodies—the one supported by the superior ecclesiastical courts, the other by the court of session. Both returned representatives to the ensuing General Assembly of 1842, but it was of course only the former who were declared by the Assembly to be duly elected, while the civil court interdicted them from sitting as members of the Assembly.

At the same meeting of the Assembly, in 1842, a vote was carried by 216 to 147, to the effect that patronage ought to be abolished. At the same time the Assembly issued a document called a "claim of right," against the "encroachment of the civil courts," which was transmitted to the government, and answered by the secretary of state for the home department, who left no hope in the minds of the non-intrusion party that their demands would be complied with. Some attempts were made in parliament to carry a measure for legalising the Veto Act, but they may be said scarcely to have had the support of any party, for those who held that the ecclesiastical courts were competent to pass such a measure into a law were not inclined practically to admit their incompetency by soliciting the intervention of parliament. A further step was in progress in the civil courts. They had already protected individuals from the effects of the acts of the church courts by prohibiting these acts from being put in execution. Proceedings were commenced for having these acts of the ecclesiastical courts annulled by the civil tribunals as courts of last resort, to which those who felt themselves injured by the proceedings of any of the constituted judicatories might apply. The court indicated that it would give redress, but these proceedings were suddenly stopped by the event called the "Disruption."

It is the practice for the General Assembly to meet on the third Thursday of May. On its so meeting, on the 18th of May, 1843, before the roll of members was made up, the late Dr. Welsh, professor of church history in the university of Edinburgh, who had been moderator or chairman of the preceding Assembly, read a protest against the constitution of the Assembly, signed by 120 ministers and 73 lay elders. A copy of this protest being left with the clerk of the Assembly, those who had signed it, and their adherents, left the Assembly in a body, and constituted in another place "the General Assembly of the Free Church of Scotland," choosing Dr. Chalmers as their moderator. This step is presumed to have been taken in consequence of the tactics laid down in the deliberations of a considerable body of the non-intrusion party who had met at Edinburgh on the 17th of the previous November, and conducted its proceedings with closed doors, being called a "convention of ministers and elders of the Church of Scotland." On the 23rd of May an "act of separation and deed of demission" was adopted by the General Assembly of the free church, and signed not only by those clergymen who were members of the Assembly, but by others who participated in their views. Thus no difficulties were put in the way of a complete separation of these persons from the benefits and burdens of the establishment. Whatever previous differences of opinion existed, and whatever objections there were to a body such as the General Assembly of the Church of Scotland, entitled to legislate and adjudicate for its own interests and according to its own feelings, being exempt from the control of the courts of law, the sacrifice of emolument and station thus made elicited general respect and sympathy, and was creditable to the sincerity of those who made it. The free church are now in possession of large sums supplied by voluntary contributions, they have established ministers in nearly every parish in Scotland, have founded a college, and are widely extending their operations.

But a fresh cause of dispute has arisen. The General Assembly of the Free Church claims the right of deciding on the fitness and orthodoxy of the ministers of the churches in connection with it. The minister of Cardross having been suspended from the duties of his office for a definite period, and for assigned causes, by the Presbytery of his district, appealed from it to the General Assembly, which increased the penalty by ordering his total removal. From this sentence the minister appealed to the Scottish law-courts. The General Assembly demurred to the civil jurisdiction, on the ground that the minister had subscribed to a declaration that he would conform to the regulations of the General Assembly. The court, however, held that this could only apply to the ecclesiastical duties, and not to his civil rights, which had been injured by the General Assembly going beyond the question which had been submitted to them, namely, whether his suspension should be removed or not. No ultimate decision has yet been arrived at (January, 1860).

FREEHOLD. An estate of freehold is defined by Britton to be "the possession of the soil by a freeman;" and by Sir William Blackstone, as "such an estate in lands as is conveyed by livery of seisin, or in tenements of an incorporeal nature by what is equivalent thereto." Neither of these definitions is sufficiently precise; both are the consequence of the tenure, not the tenure itself.

A freehold, "liberum tenementum," was simply an estate for life in tail or in fee, held by a freeman independently of the will of the feudal lord, and the term was used in contradistinction to the interest of terms for years, and lands in villenage or copyhold which might be determined by the lord at pleasure. The older law writers distinguished freeholds as of two kinds, in deed and in law; the first being the actual possession of lands for an estate of freehold; and the other, the right to such lands before actual possession taken. Blackstone divides them also into freehold estates of inheritance, and freehold estates not of inheritance. Neither of these divisions is of any real importance. In the absence of a better definition, a freehold may be described to be an estate in lands or tenements in fee simple, in tail, for the life of the holder, or for the life of another person, in dower or by the courtesy. Some offices also, held for life or in fee, are said to be of freehold tenure.

FREE-SCHOOL. [SCHOOL.]

FREE-TRADE. [TRADE.]

FREE WILL. The perplexity in which this question has been involved is perhaps mainly owing to carelessness in the use of terms; and yet, however carefully we may select and use our terms in discussing this question, it has always been found very difficult to state it clearly. Hartley puts the question thus:—He "embraces the opinion of the mechanism or necessity of human actions, in opposition to what is generally termed free-will;" and he says, "by the mechanism of human actions, I mean that each action results from the previous circumstances of the body and mind, in the same manner, and with the same certainty, as other effects do from their mechanical causes; so that a person cannot do indifferently either of the actions *A* and its contrary *a*, while the previous circumstances are the same; but is under an absolute necessity of doing one of them and that only. Agreeably to this, I suppose that by free-will is meant a power of doing either the action *A* or its contrary, while the previous circumstances remain the same. If by free-will be meant a power of beginning motion, this will come to the same thing; since according to the opinion of mechanism, as here explained, man has no such power; but every action or bodily motion arises from previous circumstances, or bodily motions, already existing in the brain; that is, from vibrations, which are either the immediate effect of impressions then made, or the remote compound effect of former impressions, or both. But if by free-will be meant anything different from these two definitions of it, it may not perhaps be inconsistent with the mechanism of the mind here laid down. Thus, if free-will be defined the power of doing what a person desires or wills to do,—of deliberating, suspending, choosing, &c.,—or of resisting the motives of sensuality, ambition, resentment, &c.,—free-will, under certain limitations, is not only consistent with the doctrine of mechanism, but even flows from it; since it appears from the foregoing theory, that voluntary and semi-voluntary powers of calling up ideas, of exciting and restraining affections, and of performing and suspending actions, arise from the mechanism of our natures. This may be called free-will in the popular and practical sense, in contradistinction to that which is opposed to mechanism, and which may be called free-will in the philosophical sense." This passage is not selected as being a peculiarly successful statement of the question, but simply because it shows with sufficient accuracy what the matter under consideration is, and that independently of the author's theory of vibrations.

Necessity, according to the common definition is that quality of a thing by which it cannot but be, or whereby it cannot be otherwise. When, in a proposition which affirms any thing to be true, there is a fixed invariable connection between the subject and the predicate, then that thing is understood to be necessary. Necessity is opposed to chance, accident, contingency, and to whatever involves the idea of uncertainty and of possible variation. It is usually distinguished into logical, physical, and moral necessity. Logical necessity consists in the circumstance that the conception of something being different from what it is, implies a contradiction or absurdity. In this sense it is necessary that two and two should be four, that converging lines, if produced far enough, should meet: thus also the eternal existence of being generally is necessary, as are innumerable other truths. Physical necessity has its origin in the established order and laws of the material universe. The necessity, in this case, differs from that formerly specified, in that it is only conditional, is a necessity of consequence. Everything that takes place in the natural world happens by virtue of certain laws: these laws are known by experience to operate regularly and uniformly; and the results of their operation are hence, with reference to them, said to be necessary. When we ascribe anything to chance, we merely state our ignorance of the law or laws to which its existence is to be referred. Physical necessity is founded on the relation of cause and effect. By tracing back this connection, we arrive at the knowledge of a great first cause, that is God, who is the only Being existing independently and by an absolute necessity. His infinity and other attributes are necessary; and it is evident that the purposes and acts of such a Being must also be necessary, being determined by that necessity by which he is what he is. He must always resolve and act with the most perfect wisdom, justice, and goodness. To affirm the contrary would be to affirm that he is different from what he is. Moral necessity has reference to the volitions and actions of rational agents, and is intended to express the connection between these volitions and actions, and certain moral causes, as inclinations, desires, or motives generally. Whether there be any connection which, strictly speaking, may be termed necessary, between such motives, and the resolutions of the human will, and the consequent actions, or whether, independent of them, the will has a self-determining power, is an inquiry which has largely engaged the attention of both philosophers and theologians. It is one of great interest, and which has an important bearing, on whatever relates to man as the subject of a moral government. [WILL.]

The doctrine of a universal necessity, or fatalism, was maintained by many of the ancient philosophers; and formed the characteristic tenet of the Stoical school. According to it, necessity was to be considered as an inevitable and all comprehending principle, to which gods as well as men were subject. Everything was conceived to exist in a necessary series of causes and effects—the whole constitution of nature—the modes and circumstances of all things without exception—being irresistibly and unchangeably determined. Hence the language of Seneca, the elegant expounder of the opinions of this sect, in his treatise 'On Providence:'—"The same necessity binds both gods and men—Divine as well as human affairs proceed onward in an irresistible stream—one cause depends upon another—effects are produced in an endless series—nothing is the offspring of chance." Democritus held opinions closely resembling the Stoical doctrine of fate; as also Heraclitus, the founder of the sect that went by his name. In modern times, the doctrine of necessity, especially in regard to the human will, has been defended by Hobbes, Leibnitz, Priestley, Hume, Kaimes, Hartley, and many others.

The universal language and practice of mankind imply a belief in a kind of free-will. To deliberate, to choose, to determine, and to act in pursuance of such determination, are expressions in every man's mouth, and things within every man's ordinary experience, both of himself and others. Every man also supposes that another will choose and determine pretty much in the same way that he himself would under the same external circumstances; that is, each man believes that every other man will be governed by motives, or will act according to motives, in the main pretty much as he would himself. When men act differently under the same external circumstances, the cause of the difference in conduct is not referred to the circumstances, in which it is here supposed that there is no difference, but to some difference in the persons. We believe, therefore, that circumstances move men to act, but that we have at least a certain power of weighing these various motives and giving the preponderance to one or another, and that different men possess and exercise this power in different degrees. This may be called, in a sense, a free exercise of the will, and every man, at least who is of sound mind, believes that he has this power, and is supposed by others to have it.

The belief that man possesses this power is the foundation of laws which forbid acts under certain penalties. All legislators have believed that the knowledge that a certain punishment will follow a certain act if detected, operates in some degree on those who are disposed to do the forbidden act; that the persons who are by any motives led towards such act may, and as a general rule will, deliberate on the penalty attached to the act before they do it, and will often be prevented from doing it by a comparison of the advantage which they expect to derive from the act, with the certain penalty attached to it. Many persons do not violate the law because they have been brought up in habits of uniform obedience to it, and therefore the penalties of the law have little or no effect upon their conduct; but it will hardly be disputed that the fear of punishment has some effect on many men, and is a motive which, operating on the mind and operated upon by the mind, produces self-restraint. The enactment of penal laws supposes a power in men to determine how they will act; or, in other words, it supposes at least that motives can be presented to men which shall in some way and in some degree determine their conduct.

That men, then, do act under the influence of motives, and that they have also the power of weighing motives, is universally admitted, and for all practical purposes it is immaterial to inquire any further. A man subjects himself to a certain discipline, he educates his children in a certain method, and legislators forbid men to do a variety of acts,—all acting under the belief that the discipline, the education, and the rules of law are so many motives, which, by constantly operating on the mind, will produce on the whole a certain line of conduct in those who are the objects of them.

But it has been already said, that the external circumstances or the motives being the same, two persons will often act differently under them. As the external motives are by the supposition the same, there is some difference in the persons which causes the difference of conduct. Under the same external circumstances, one man will violate the law, and another will not; one will steal and rob, and commit murder, and another will not. It is generally said that the transgressor of the law is punished on the supposition that his act is voluntary; that he could, if he chose, have acted differently. Practically, he who executes the law will not trouble himself with the question whether a particular individual could have acted differently under the circumstances: if it is shown that such a person possessed the ordinary understanding of mankind, he will see no reason for remitting the punishment; because he believes that in most cases, if not in all, the penalty attached to a particular act will operate to deter people from doing it. The question of an absolute free-will, then, does not concern a legislator. It is enough for him to present the proper motives for acting or not acting in certain ways, if he believes that such motives will on the whole produce the conduct which he requires. Nor does the question of absolute free-will concern any other person who has to direct or operate upon others. If he believes that he can place such circumstances around persons, or present to them such motives, as will cause a determinate course of action, it is unimportant whether he believes that the course of action is necessarily determined by these circumstances, or by these concurring with other circumstances, or that the persons who are under their influence do in some way or other choose and determine to act as he wishes them to act.

But if we examine more closely any particular act of a man's life, suppose it to be an act which has about it all the marks of slow deliberation, in what sense can we say that this is an act of absolute free-will? The ordinary language of mankind assumes the existence of choice,—deliberation,—and yet it does not permit us to maintain that every act is an act of absolute free-will. If it is a virtuous act, we do not barely ascribe it to a man's careful consideration of all the motives which at the time operated on him; we speak of his habits, his education, his character, as the things which would ensure his acting on a given occasion in a determinate way, or, if we so choose to express it, as securing that exercise of the will which is called a proper exercise. And we make the like remarks of a man who has deliberately done a bad act. In both cases we do not attribute the whole conduct of the man, nor yet the greater part of it, to his then determination. We refer to antecedent circumstances as co-operating to this determination. This is the language of all mankind; and the language of all mankind, when rightly analysed, is the true exponent of universal opinion. Confused and perplexed as it often is, it contains within it implicitly the elements of all philosophy. Now, when we once refer to antecedent circumstances as affecting our determination under the motives that are presented on any one occasion, we give up the theory of an absolute free-will, for we make every act of will depend, in some degree at least, on something prior; and that something, again, must by the like reasoning depend on something prior to it; and thus we have an infinite chain of events, and consequently we find ourselves engaged in an inquiry which is beyond the reach of our capacity. Thus, if, as Hartley says, "by free-will be meant a power of beginning motion," no person can, consistently with his own ordinary language and that of others, maintain this proposition; if he does, he will contradict himself almost as often as he speaks.

Human actions, then, are, in some degree at least, subject to the same general laws to which other events are subject. Every human action has its antecedents, on which it in some degree depends; but whether every human action is as necessary, in the sense in which Hume explains the term necessary, as the other phenomena which we see, is precisely the matter in dispute. (Hume, Essays, 'Of Liberty and Necessity.')

When it is said that every event and every human action has its antecedent on which it depends, it must not be understood that it is meant, here at least, to maintain anything else than this. Such antecedents are events which, according to our experience, precede the given event uniformly, or at least with sufficient uniformity to generate in our minds the notion of a certain order or continuity; for though any given antecedent event is called the cause of any event which uniformly follows it in our ordinary mode of speech, we here mean to express nothing more than the fact of this uniform sequence. The utmost that we can say is, that the antecedent event is, according to the constitution of the universe as known to us, a necessary condition to the subsequent event. Neither heat, nor moisture, nor anything else that we can name, is the cause or a cause of a seed vegetating and producing a plant like that from which it came. Heat and other things are conditions of vegetation as known to us. The efficient cause can only be one, which must be perpetual, and beyond which we seek for no other. This efficient cause is no law of nature, a term which is incapable of all strict analysis. It is the will of God to those who admit the existence and omnipotence of the Deity. To those who do not, if there be such, it is something which has never yet been explained.

Now as all human actions have their antecedents, without which, according to our experience, they could not be, it follows that there are certain antecedents of every action which are its conditions, without which such action would never be. This cannot be denied. It is the ordinary language of mankind expressed in a different form. But still it is perfectly consistent with this to speak of man exercising his will, that is, operating on the motives which are presented to him. On any given occasion man is subjected to various momenta, and it may be admitted that each man will be directed by that which to him at the time is the strongest. But if a power of estimating different motives be admitted to exist in the mind, and to exist in different men in different degrees, the strength of the motive is not its own strength acting on the passive mind; it is the activity of the mind which according to its power comprehends the motive completely or incompletely.

If the analogy is sound between human actions and other phenomena, and if in other phenomena the antecedents or conditions are not causes, so neither are the antecedents or conditions of human actions to be viewed as their causes. Man is constantly subjected to various momenta, motives, or circumstances, as they are often called, without which he would not act as he does act. These momenta are traced back by an infinite series to the first cause of all, just as in the bare physical phenomena, if we trace them far enough, we must ascend to a first cause. If the analogy then is complete between man's acts and other phenomena, the operation of all these complicated conditions in some way determines the acts of man; but how it determines them we cannot tell. There is no person who maintains the doctrine of absolute free-will who will contend that man can set his will in opposition to that of God. It is possible to conceive that God does will to let man have free action within certain limits, but not further; and all our forms of speech do either expressly or by implication admit that our will is free to a certain extent, which we cannot exactly define, but that it is not absolutely free. It may be objected that to deny an absolute free-will destroys the distinction between actions; that it represents the Deity as the cause of vice and misery. But even if it should be so, that will not prove a thing to be false which is established by the sound exercise of our understanding. No such consequence however does follow. To God we attribute the origin of everything; and consistently with this we must say that he permits vice and misery to exist in the world. It is a consequence of man's nature as he is constituted, and under the circumstances in which he is placed, that he has acted and does act in such a way as to cause misery to himself and others.

It must therefore be assumed that God has, for reasons unknown to us, so constituted man that he does not always act in the way that is most consistent with his own happiness and the happiness of others. The vicious conduct of many men in life is an object of disapprobation to others, and in all societies that conduct which is injurious to the existence of such societies is visited with penalties. Thus a vast majority of mankind see that certain acts are injurious to the general happiness, and it is one main object of society to prevent such acts. As God permits society to exist, we may assume that he wills it to exist, and that he wills generally the means by which society attempts to secure its own existence. It is a consequence of this that he disapproves of the conduct of those whose acts endanger the existence of society. We cannot say that he does not will it: it exists, and therefore is consistent with his general will. We are compelled therefore to apply to him by analogy such terms as are applicable only to our own limited capacities: and we say that he wills generally that all things shall be as they are, but that he disapproves of some. That he permits man so much liberty of action as to render it necessary for society to be vigilant against the evil doers who would disturb its repose, is no more an imputation upon his goodness than that he permits fire, tempest, and war and pestilence and famine to thin the numbers of mankind. So far as concerns those who suffer, it is the same thing whether they suffer from the hand of man, or from causes over which he has no control. It is consistent with all experience to say that the Deity has willed that man shall suffer pain both through the agency of matter and through the agency of his fellow-men. Now if we shall assume that God only wills our happiness in the sense in which many persons understand it—which would, according to their notions, exclude all pain and suffering—whatever misery happens through man's misconduct must be against his general will, and can only result from man having an absolute free-will, and sometimes exercising it in a way different from the Deity's wishes. There is no evading this difficulty. An absolute free-will in man or in any other being is inconsistent with the omnipotence of the Deity, and it is, as already shown, contradicted by all our observation of the mode in which man is operated upon by motives and circumstances. But there is nothing which prevents us from attributing to man, as we do in our daily expressions, a power of determining his acts, under given circumstances, in one direction rather than in another, and in a wrong in preference to a right direction. And it is further admitted by the universal language of mankind, that the same man who acted wrong under one set of motives, might and would have acted right if he had been influenced by other motives; and these motives to right action, it is also admitted, may be and frequently are external circumstances over which he has no control. It is true that a man may so discipline himself, that, in any given circumstances which may arise, he may have motives at his command which shall enable him to act in the right direction, a power which Hartley speaks of in the passage at the head of this article. But if some men can do this, all cannot; and even in the case of him who can do it, we may always trace the origin of this power to some external circumstances over which he had no control. Man's will then is circumscribed by the constitution of things, of which he is a part. He is placed in circumstances in which he is operated upon by various motives to action. If it is said that he must be determined absolutely by that which is the most powerful, this is only another mode of saying that of various forces tending to make him move, the strongest will carry him in its own direction. But in truth the words force, motive, and others of a like kind, are apt to lead us to false analogies: and these terms require explanation.

Every man believes at the time when he acts with deliberation that he has a capacity for exercising a free-will. But he also knows that circumstances may prevent deliberation. Thus it is a common case for a man to allege that if he had not been alarmed or hurried, he would have acted differently; or in other words, he would have been enabled to deliberate and decide better. No man considers it to be a case where the will is properly concerned when his action is thus impeded. And there are numerous like cases in life in which in fact there is no choice or deliberation, and consequently no real exercise of the will. The power, then, whatever it may be, to deliberate and act, is often suspended or not exercised. In most cases we act from habit in the general course of life; in other cases from impulse; and when we act from impulse, there is no deliberation or determinate will. It appears then that our will is not always exercised when we act, but that when it is exercised we are conscious of a capacity to weigh deliberately the various motives or grounds of action as presented by our own mental activity. Now if we say that the strongest motive thus presented must prevail and determine to action, we may, as above observed, be misled by a false analogy. The motive may be called a moving power; and if so, it must have its effect: but to deny the mind all power in itself to resist the motive, is the same thing as to consider it an inert mass operated upon solely by an external force. It is the same thing as to make the mind of man a recipient of sensuous phenomena without any power to operate on them. The systems of philosophy which view the mind as such a recipient will be consistent in making it yield to the strongest motive without an effort of its own. Those systems which assign to the mind a power of operating on impressions may consistently admit a power of determining which of them it will obey.

God the creator of the universe is omniscient. To him time past, present, and future, is one. We conceive him as knowing all things, willing all things, directing all things. But our acts of free-will then, it may be urged, are God's will, and therefore not man's. Therefore free-will in man in any sense contradicts our notion of God's power. To this we answer, that man's power to will is here considered as a fact of which our daily experience convinces us; and further, that the existence of this power is a legitimate deduction from the nature of man's mind, which is here supposed to have an activity independent of all sensuous impressions. It is admitted that if our actions are viewed in reference to the power of God, as we conceive it, we cannot reconcile our notion of the freedom of our actions with our notion of the power of God. But there is no contradiction here. Contradiction implies that the things between which it arises are equally within the cognisance of our understanding. It is no contradiction to say that God wills all men's acts, and that man wills his own. Both things may be true, though we cannot comprehend how it is so.

FREEDMAN. [Slave.]

FREEMAN. [Municipal Corporations.]

FREESTONE. A term applied by practical masons to those descriptions of building stones which are able to be worked with the ordinary mallet and chisel, in contradistinction to those which are worked by the pick, or which it is necessary to stun. The various descriptions of oolites, sandstones, limestones, and the softer kinds of grits, are classed as *freestones*, and they may all be sawn, either by the plate or by the toothed saw; the granites, the millstone grits, the burrs, and the lavas or basalts, are not included in this class: nor are the slate rocks, though they are capable of being sawn by the plate saw. In fact the term freestone is only applied to those materials which are susceptible of easy conversion to the ordinary purposes of building, and the distinctly marked cleavage of the slate rocks renders this operation almost impossible in their cases.

FREEZING is the solidification of fluid bodies by the abstraction of the heat necessary to their fluid form. It occurs by the effect of natural cold in many liquids; and most of them may be frozen by an artificial reduction of temperature. It is to be observed, that what are termed the *freezing points* vary greatly in different fluids, and their remaining such at different temperatures depends upon the different degrees of power with which they retain the heat necessary to fluidity. Liquids may be considered as solids in combination with heat, which exists in them in a latent state, and which they give out as sensible heat when they return to the solid form.

In passing into the solid state, certain liquids undergo a sudden and often considerable change of volume, which may either be an enlargement or a diminution. For example, when mercury is cooled to —39° Fahr., a great and sudden contraction takes place; so much so, that when observed in a thermometer, it falls through a considerable number of degrees, and the whole of it may retire into the bulb. The reverse of this takes place in the case of water. In passing from 38·8° to 32°, its freezing point, it undergoes a regular expansion; and in passing into the solid state it undergoes a further expansion, amounting to one-seventh of its bulk. And so irresistible is this expansion, that rocks are rent asunder by the freezing of water in their crevices; vessels and pipes containing water are burst; and it was calculated, in the case of a strong brass globe, filled with water and closed by a screw, and burst by the freezing of the water within it, that the force necessary to produce this effect amounted to not less than 28,000 lbs. When liquid phosphorus is gradually cooled it regularly contracts; and, passing into the solid state at about 100°, it undergoes a sudden and considerable contraction. The same observation applies generally to oils in the process of freezing, and it has been remarked that, in general, bodies which do not crystallise in freezing undergo a sudden contraction, while those which do so crystallise undergo a sudden expansion. Sulphuric acid, however, in becoming solid, or passing from the solid into the liquid state, does not appear to suffer any change in volume. Cast iron, bismuth, and antimony expand in solidifying; the other metals, however, contract in doing so.

What are called *freezing mixtures* are such as produce cold by and during the liquefaction of their solid ingredient, and the consequent absorption of the heat on which its solid form depended. Such mixtures reduce the temperature of substances immersed in them on the principle of the transfer of heat, which always takes place from hotter to colder bodies when exposed to each other.

The process used by confectioners for producing cold is by the mixture of ice and common salt, which, both liquefying, absorb so much heat, or in other words produce as much cold as will reduce the thermometer from the usual temperature to the zero of Fahrenheit's scale, or even rather below it. If, however, freshly fallen snow be used instead of ice, then the fluidity is more suddenly produced and the cold is more intense.

In freezing mixtures, the substances combined have such an affinity for each other that when intimately blended they combine chemically, and in doing so liquefy. The operation should be so arranged that no heat be furnished either by the vessel in which the liquefaction takes place, or from any external source. Under such circumstances, the heat absorbed during the liquefaction must be furnished by the materials of the freezing mixture (in which case the reduction of temperature will be proportional to the quantity of heat rendered latent), or by the body which it is intended artificially to cool or to freeze.

The reader will find in works on chemistry many recipes for freezing mixtures. One or two examples will suffice here. With equal weights of fresh snow (or pounded ice) and common salt a temperature of —4° Fahr. can be maintained for many hours. A mixture of three parts crystallised chloride of calcium and two parts of snow will produce a depression of temperature sufficient to freeze mercury. If the vessel in which the materials are to be mixed and the chloride be cooled to 32°, a temperature of —50° can be produced. The most powerful freezing mixture is formed by dissolving solid carbonic acid or solid nitrous oxide in sulphuric ether. In this way temperatures of —120° to —146° have been obtained, at which alcohol passed from the consistency of oil to that of melting wax. For more moderate temperatures, certain salts easily procurable may be used. Thus, 4 ozs. of nitre and 4 ozs. of sal ammoniac, both in fine powder, mixed with 8 ozs. of water, will reduce the thermometer from 50° to 10°. Equal parts of water, of powdered crystallised nitrate of ammonia, and of powdered crystallised carbonate of soda, will lower the temperature from 50° to —7°.

FREEZING APPARATUS. The first apparatus of this kind was an air-pump contrived by Sir John Leslie for the purpose of freezing liquids in vacuo.

It is well known that liquids evaporate more readily when the atmosphere is removed from their surfaces than when they are subject to its pressure; the caloric producing the evaporation being that which exists in the liquid itself, and that which, in consequence of the disturbance of the equilibrium, enters the liquid from the neighbouring bodies: hence, if there be a quantity of sulphuric ether in a vessel under the receiver of an air-pump, and in it there be placed a vessel or tube containing a small quantity of water, on exhausting the receiver the ether will rapidly evaporate, and, the operation of exhausting being continued, the vapour will be carried off as fast as it is formed. The caloric in the water is withdrawn at the same time, and at length the water is converted into ice.

In order to produce the congelation of water by a rapid evaporation from its own surface under the exhausted receiver of an air-pump, Leslie introduced into the receiver a shallow vessel containing highly concentrated sulphuric acid, above which was placed the vessel containing the water. The air being extracted as quickly as possible, the vapour—which, in consequence of the removal of the pressure, escaped continually from the water, even at the medium temperature of the atmosphere—was, by the strong attraction of the acid for it, absorbed as fast as it rose; and in two or three minutes the quantity withdrawn from the water was sufficient to allow a congelation of the water to take place. Instead of sulphuric acid, any substance which (as dry potash, muriate of lime, or calcined powder of basalt) has a strong attraction for humidity may be used; but the first, if highly concentrated, is the most efficacious.

The air-pump employed for the purpose by Leslie was constructed in the usual manner, but of large dimensions, in order to obtain ice in considerable quantities, and the receiver was a segment less than a hemisphere, that the air contained in it might be extracted as speedily as possible. The sulphuric acid or absorbent earth was contained in a shallow vessel of glass, nearly equal in diameter to the base of the receiver; and from the centre of the vessel rose a hollow cylinder, on the top of which, above the acid or earth, rested the cup of glass, or rather of unglazed earthenware, which contained the water to be frozen. Machines of this kind have been varied in different ways, the last and most successful of which produced great blocks of ice by the evaporation of ether, and the process of welding slabs of ice as fast as they were formed. The ether was conducted into a separate chamber and condensed, so that it could be used over and over again with little or no loss. This apparatus was patented by Mr. Harrison, "for producing cold by the evaporation of volatile liquids in vacuo, the condensation of their vapours by pressure, and the continued re-evaporation and re-condensation of the same materials." A detailed account of this apparatus with diagrams, is given in the 'Pharmaceutical Journal,' xvi, 477, but we may state briefly that the apparatus consists first of an air-tight metallic vessel, from which air is removed by a pump, and in which ether is kept constantly evaporating; secondly, of an air-tight metallic vessel, into which the ether vapour as it is removed from the former vessel is condensed under pressure; thirdly, of a pump, by which the vapour of the evaporating ether is withdrawn from the first vessel and forced into the second, where, as the pressure increases, it assumes the liquid state ready to be again evaporated. Thus the process is continuous, and there is no appreciable loss. The first and second vessels are surrounded by water, and the cold caused by the rapid evaporation of the ether in the former vessel causes the water surrounding that vessel to freeze, while there is, of course, a corresponding elevation of temperature in the water which surrounds the other vessel where condensation takes place. The only expense is said to be for motive power, which is supplied by a steam-engine of 10-horse power, and it is stated that 1 ton of coal economically applied, is equal to the production of 4 tons of ice. The apparatus was exhibited in London in the summer of 1858, and is now, we believe, in Australia.

Leslie, by means of the like apparatus, succeeded in freezing mercury by the absorption of caloric from a coating of ice in which the bulb of a thermometer was enveloped. In the performance of this experiment, the thermometer was suspended from a wire which, passing through a collar of leathers at the top of the receiver, could be raised and lowered at pleasure. A cup of water was placed above the vessel containing the sulphuric acid; and the bulb of the thermometer, after being lowered into the cup, was drawn up and suffered to lose caloric by the evaporation of the adhering water, in the exhausted receiver: this process being repeated several times, the bulb was at length covered with a film of ice. The cup of water was then removed, and the thermometer, having its bulb thus covered, was allowed to remain suspended about half an hour above the sulphuric acid, the exhaustion of the air being made as complete as possible, so that the column of mercury in the barometer-gauge was within 1-20th inch as high as in a barometer which indicated the density of the external air. On re-admitting the air, and removing the receiver, a portion of the mercury in the ball of the thermometer was found to be frozen. In another experiment, the mercury was inclosed in a mass of ice worked by heat into the form of a cup, and suspended above the sulphuric acid in a small net made of wire. The mercury was introduced into the cup of ice, and on it was poured a small quantity of water. On exhausting the receiver, the water was immediately frozen, so that the mercury was then completely enveloped with ice; and in a few minutes, on removing the receiver, the mercury was found to be wholly frozen. [EVAPORATION.]

FREEZING AND MELTING POINTS, a term applied to the temperatures at which certain liquids become solid, or certain solids become liquid. Thus, mercury becomes solid at —39° Fahr., oil of vitriol at —30°, bromine at —4°, water at 32°, phosphorus at 111·5°, and so on. These points are also entered as *fusing points*. [FUSION.] Thus we say that yellow wax, on the reduction of the temperature, becomes solid, and also, on being heated, begins to fuse at 143·6°, iodine at 224·6°, sulphur at 239°, tin at 451°, nitrate of soda at 591°, lead at 620°, nitrate of potash at 642°, zinc at 773°, antimony at about 900°, silver at 1773°, copper at 1996°, gold at 2016°, cast iron at 2786°, and wrought iron at about 3280°.

Although there is nothing essentially different in the passage of water and cast iron from the fluid to the solid state, yet for temperatures above that at which water becomes solid, the term *freezing* is not usually applied, but rather the *point of solidification*, or, as before stated, the *fusing point*. It is remarkable that the freezing point of water, a liquid which expands in freezing, becomes lowered to a minute but measurable extent by exposing the water to strong pressure. According to Professor Thomson, of Glasgow, a pressure of 8·1 atmospheres lowers the freezing point 0·106° Fahr., and a pressure of 16·8 atmospheres 0·232°; whereas, in bodies which contract in becoming solid, the melting point is found to be raised by pressure. Thus, spermaceti, which under atmospheric pressure became solid at 117·9°, under a pressure of 150 atmospheres solidified at 123·6°.

FREEZING MIXTURES. When certain substances are brought into intimate contact, a more or less considerable degree of cold is produced. Such mixtures are denominated freezing mixtures.

The principle on which the action of freezing mixtures depends is the following. When solids assume the liquid condition a large amount of heat is always absorbed or rendered *latent;* and when liquids assume the gaseous condition a large quantity of heat is also thus taken up. For example, when a piece of ice having a temperature of 32° Fahr. is plunged into its own weight of water at 174° Fahr., the ice immediately begins to liquefy, but during that liquefaction enough heat is absorbed by it to bring down the temperature of the hot water to that of the ice itself; 142 degrees of heat having thus disappeared, the thermometer taking no note of it. Again, the same body, water, when exposed in a vacuum under favourable circumstances, takes up so much heat in assuming the gaseous condition, that portions of it are converted into ice; the one part that boils away robbing the remainder of the heat that kept it in the liquid state.

From the fact that water in passing from the solid to the liquid state has the property of taking up, or rendering latent, a greater amount of heat than any other substance, it follows that solid water must be a powerful agent in producing artificial cold, and this is in practice found to be the case. It is employed in the form of powdered ice or snow, or sometimes combined with certain salts, constituting their so-called water of crystallisation.

Before giving the formulæ for some freezing mixtures, it will be as well to premise that, as a general rule, the substances composing them should be finely powdered, rapidly mixed, as large a quantity as wanted made at one operation, and the whole placed in vessels possessing the smallest possible amount of conducting power. The greatest amount of cold obtainable with the substances used, is only produced when they themselves, as well as the vessels used in the operation, are all previously cooled by freezing mixtures.

In addition to the freezing mixtures given under FREEZING, the following may be mentioned as useful frigorific agents :—

Mixtures.	Parts.	Thermometer sinks	Degree of cold produced.
Nitrate of ammonia	1	From +50° to +4°	= 46°
Water	1		
Chloride of ammonium	1	From +50° to +23°	= 27°
Water	4		
Sulphate of soda	3	From +50° to −30°	= 80°
Dilute nitric acid	2		
Sulphate of soda	6	From +50° to −14°	= 64°
Nitrate of ammonia	5		
Dilute nitric acid	4		
Phosphate of soda	9	From +50° to −12°	= 62°
Dilute nitric acid	4		
Sulphate of soda	8	From +50° to −3°	= 53°
Hydrochloric acid	5		
Snow	12	From +32°=57°	to −25°
Common salt	5		
Nitrate of ammonia	5		
Snow	8	From +32° to −27°	= 59°
Hydrochloric acid	5		
Snow	4	From +32° to −40°	= 72°
Chloride of calcium	5		
Snow	1	From −40° to −73°	= 33°
Chloride of calcium (crystals)	3		

The rapid evaporation of ether *in vacuo* has recently been rendered available for the manufacture of ice upon a large scale, and as the ether is evaporated and condensed again by steam power, it may be truly said of the process that it produces ice by the combustion of coal. It is found that the combustion of one ton of coal yields about five tons of ice.

For common experimental purposes the most convenient freezing mixtures are the sulphate of soda and hydrochloric acid, or salt and powdered ice.

FREIGHT. The charge made for the carriage of merchandise in a ship, and the amount of which is generally specified in the bill of lading. [BILL OF LADING.] It frequently happens that the whole ship is hired by a merchant for the performance of the voyage, and in this case a certain amount of freight is paid without reference to the quantity of goods actually put on board, which may be sufficient to fill the ship, or any quantity short of the same. In such cases the mode of payment is part of the matter of agreement between the ship-owner and the merchant, and the instrument by which this and other stipulations are set forth is called a charter-party. Where no such instrument exists, and the shipper of goods does not stipulate for the right of using the entire portion of the ship appropriated to the reception of her cargo, the amount of the freight, as well as the mode of payment, is usually inserted in the bill of lading. Where this is not done, the freight is by law considered due on the part of the merchant on the delivery of the goods, and the owner or master of the ship may, if so minded, demand payment of the same, package by package, as the same are delivered. In almost all branches of trade, however, some custom in this respect has arisen which is ordinarily pursued, and the legal rights of the ship-owner are not enforced in this respect. In London, where the greater part of the merchandise brought from foreign countries is delivered into the custody of one or other of the incorporated dock companies, a custom has arisen of arresting the goods in their hands, so that they cannot pass away from the original importer until the ship-owner, or some person acting on his behalf, has signified in writing that the freight has been paid. If goods are damaged on board the ship, through the carelessness or wilful neglect of those in whose charge she and her cargo are placed, so that the owner of the ship is held to be liable for the amount of the damage, this cannot, but with the consent of the owner or master, be set off against the amount of the freight, which must under all circumstances be paid, and the merchant must afterwards substantiate his claim to compensation for the amount of the damage.

FRENCH CHALK. [COLOURING MATTERS.]

FRESCO PAINTING. A painting is said to be *a fresco*, or painted in fresco (*sul fresco intonaco*, upon the fresh coat), when it is executed in water-colours upon a freshly plastered wall, while the plaster is still wet; or upon wet plaster spread upon a wooden frame or any other object. Fresco is the most noble and imposing of all methods of painting. It does not admit of the softness, delicacy, or finish of execution, or the richness and depth of colour, of oil-painting; but the very want of the inferior beauties compels the painter to rely upon the highest intellectual conception, composition, drawing, and expression, united with a largeness of style and freedom of handling, which can only result from great technical knowledge. It is therefore only in the hands of the great painter that fresco is likely to be really successful.

Colouring in fresco was practised by the ancients, though it has not yet been shown that they *painted frescoes*. Some of the walls at Pompeii are coloured in fresco, but their decorations are executed in some species of tempera upon the fresco coloured wall. This is evident, because in many places the paintings have cracked off, and exposed the original colouring of the ground in perfect freshness, and the same as the rest of the wall where no decorations are painted. The Roman term equivalent to fresco is *udo tectorio*, and it is used by Pliny ('Hist. Nat.' xxxv. 31), who gives directions as to what colours it is safe or unsafe to apply in this manner. Vitruvius (vii. 3) explains the mode of preparing the walls for this species of colouring, and describes a method of varnishing them when coloured, to preserve them. They first covered the wall with a layer of ordinary plaster, over which, when dry, they placed successively three other layers, of a finer quality, mixed with sand; above these they placed again three layers or coats, of a composition of chalk and marble-dust, the upper coats in this case being each added before the under one was dry, and successively of finer qualities. By this elaborate process the plaster formed a solid mass, as it were, of marble; was capable of being cut away and transported in a wooden frame to any distance; and sometimes even tables were formed of it. (Vitruvius, ii. 8; Pliny, xxxv. 49.)

The process of varnishing the walls when coloured, Vitruvius terms (vii. 9) a Greek practice, called *καῦσις*, "a burning." When the wall was coloured and dry, Punic, or purified and bleached, wax, melted and tempered with a little oil, was rubbed over it with a hard brush; this was made smooth and even by applying a *cauterium*, or iron pan filled with live coals, to the surface, near enough to melt the wax: it was then polished with a linen cloth. [ENCAUSTIC PAINTING.]

Fresco was not generally practised by the early Italian painters, and it appears to have been first used in the 14th century, simply as a preparatory process, the work being finished in *tempera*. The earliest works in *buon fresco* are in the Campo Santo at Pisa (about 1390), in the church of Assisi, in the cathedrals of Orvieto and Siena, and in San Miniato and Santo Spirito at Florence. Thenceforward the practice of fresco improved with the progress of the art of painting, until it reached its greatest excellence in the hands of Michel Angelo, Raffaelle, and their contemporaries, whose greatest works were all executed in this manner. With the decline of the art, fresco fell gradually into disuse. Its revival dates from about 1816, when the young German painters, Cornelius, Overbeck, Veit, and Schnorr, undertook to paint with frescoes the Villa Bartholdy at Rome. Ludwig, then crown-prince, afterwards king of Bavaria, warmly patronised the new art, and at a large expenditure, continued through many years, afforded the young painters ample opportunities for a thorough study of the works and processes of the old masters; and, in the magnificent Glyptothek, the Ludwigs-Kirche, the new palace, and the Pinacothek, at Munich, of exercising their own powers on a colossal scale. With Hess, Kaulbach, and other German artists, these, the earliest practitioners, have succeeded in restoring the art to nearly all its former supremacy; and many of their paintings rival in purpose and magnitude, if not in power, the most important works of the great masters of Italy. Fresco has also been practised to a considerable extent in France, and some excellent works have been produced there. In our own country great attention was called to the process, by the recommendation of the Commissioners of the Fine Arts that the new houses of parliament should be adorned with fresco-paintings. As is well known, in pursuance of this recommendation, a large number of fresco-paintings have been executed with more or less success by artists of eminence in the house of lords, robing rooms, peers' and commons' corridors, and various chambers. Some of these are highly effective works, but as a rule English painters have not as yet acquired sufficient familiarity with the process to work in it with the necessary freedom and decision. Of the earlier frescoes, especially those of subjects from the English poets in the upper waiting hall, some have greatly faded or otherwise changed in appearance, owing as is believed to damp in the walls. In the frescoes recently executed, and now in course of execution, much greater precaution is taken to ensure their permanency. The example set in the new palace of Westminster has not hitherto been so extensively followed in this country as might have been anticipated. The principal frescoes since executed here have been a series in a garden saloon at Buckingham Palace; those by Mr. W. Dyce, R.A. (already distinguished by his frescoes in the new palace), above the altar at All Saints', Margaret Street; and the 'School of Legislation,' by Mr. Watts, which covers the north end of Lincoln's Inn Hall. This last is probably the largest fresco executed since the time of Michel Angelo, with the exception of the 'Last Judgment,' by Cornelius, in the Ludwigs-Kirche, Munich: the Lincoln's Inn fresco is 50 feet by 34; that at Munich, 60 feet by 30.

1. *Walls.*—We now proceed to give a more particular account of the processes employed in fresco-painting. Frescoes are painted on four different kinds of walls: in the old gothic buildings, on ashlar walls covered with a thin coat of plaster; in more recent buildings, on brick and rubble walls; and in some of the most recent edifices, on lath covered with various thicknesses of plaster. In many old buildings the walls as built were very uneven, and no attempt was made by the plasterer to correct a defect so detrimental to the appearance and preservation of a painting, through the settlement of dirt and the injury it undergoes in cleaning. The plaster is liable to fall away from ashlar walls, especially if the stones are large and the joints close, as in the cathedrals of Siena and Orvieto; in the church of Assisi, where the stones are small and not closely jointed, the plaster has a better hold and is generally still firm, but ashlar walls condense the damp and are the worst of all walls for frescoes; brick, rubble, and lath are much better, and nearly all equally good if well constructed. Mr. Wilson, then director of the Government School of Design, in his report to Her Majesty's Commissioners on the Fine Arts, respecting the state of the middle age frescoes and other mural paintings—to inquire into which subject he was expressly sent into Italy—ascertained upon what species of wall the various frescoes of the most eminent Italian painters were executed, and reported as to the actual condition of those works, with reference to the walls on which they are painted, and the result is, that those executed on brick are the most general, and in the best state of preservation: equality of surface being a great advantage which the brick wall has over the rubble wall. Many of the best of the old frescoes however are upon rubble walls, and unfortunately upon badly constructed walls of this description, as those of Santa Maria Novella at Florence, and St. Cecilia at Bologna. The older walls of the Vatican are of rubble, or of alternate courses of rubble and brick, or rubble and tufo, a coarse porous volcanic stone, and are thickly coated with rough-cast, or coarse plaster of sand and lime mixed. The 'Trionfo della Morte,' by Orcagna, in the Campo Santo at Pisa, is painted upon lath, and is the best preserved fresco there. By this provision his work was protected from the damp which rises from the soil, and that which infiltrates from the roof; the sea air therefore cannot have injured the other frescoes, or it would have injured this likewise. There are many frescoes at Florence and at Venice, on lath, and all are in tolerable preservation; many vaulted or coved ceilings are of lath, plastered above as well as below. The frescoes in the new palace at Westminster have been executed on lath, but in the most recent ones the laths have been fixed to a panel of slate 1½ inch thick, a space for air half an inch deep being left between the laths and the slate by means of battens at the ends: the method is shown by aid of diagrams in the 11th Report of the Commissioners of the Fine Arts.

2. *Plaster and Lime.*—The method of plastering the walls for painting has been nearly uniform in most ages. The walls of the baths of Titus at Rome are covered first with a layer about half an inch thick of coarse sand and lime; above this a thicker layer of lime and pozzolana, with an admixture of sand and pounded brick; the third and upper coat is of lime and pounded marble. The third loggia of the Vatican, painted by Giovanni da Udine, is much the same as this; the first layer upon the lath is a thin coat of coarse sand and lime, the second is also a thin coat of lime and pozzolana, and the third is of lime and marble-dust, but not finely pulverised.

In all plastering for fresco painting the lime should be rather old, even in the first coat or rough-cast; but it is indispensable in the last coat, or *intonaco*, upon which the painting is executed. Various directions are given by writers on art as to the proportions of lime and other materials for the several coats, and they all agree in essentials. The oldest writers are Cennino Cennini and Leon Battista Alberti. Cennini's 'Trattato della Pittura' was written in 1437, but was first published in Rome by the Cavaliere Trambroni in 1821; an English translation of it, by Mrs. Merrifield, was published in 1844. The work of Alberti, 'De Re Edificatoriâ,' though written after the treatise of Cennini, was published shortly after Alberti's death, in 1485, by his brother Bernardo.

Cennini recommends that both lime and sand should be well sifted, and if the lime be rich or recently slaked, that there should be two parts of sand to one of lime; that enough for fifteen or twenty days should be prepared at a time, and that it should be kept for some days to render it less caustic, for if too caustic, the *intonaco* will blister. Alberti speaks of three coats as necessary: in the first, or rough-cast, he recommends the use of pit sand and pounded bricks; in the second, or sand-coat, he recommends river sand; in the third coat, which should be white, he recommends pounded white marble instead of sand; but finely sifted well-washed river sand makes a superior *intonaco*: these three coats were called by the Italians—the *rinzaffato*, rough-coat; the *arriciato*, sand-coat; and the *intonaco*, the fresco ground. Cennini speaks only of two coats, both of which he terms *intonaco*. Similar directions in essentials are given by Armenini, in his treatise 'De' Veri Precetti della Pittura,' Ravenna, 1587; at the end of the treatise on perspective, 'La Prospettiva,' by Andrea Pozzo, Rome, 1693; and in still greater detail by Palomino, in his work 'El Museo Pictorico y Escala Optica,' Madrid, 1715. Various other writers also have given more or less concise directions for fresco painting, but they contain scarcely any information that is not given at greater length in the above-mentioned works, from which Sir C. J. Eastlake made several important extracts in an Appendix to the 'Report of the Commissioners on the Fine Arts' for 1842. What follows here from the directions of Cornelius, Hess, and other eminent contemporary fresco painters, from the same Report, agrees in every material point with the advice of those earlier practitioners in the art.

The selection of the limestone to be employed in fresco painting, both for the ground and for the white, is a matter of great importance; it should be nearly pure carbonate of lime, and should contain as few foreign materials as possible. The early Italian painters found Travertine the stone best fitted for the purpose; it is in great abundance in the Roman Campagna, being a deposit or calcareous sediment from the streams of water which run from the Apennines, which consist in Central Italy chiefly of a soft limestone. Travertine consists of a carbonate of lime, with an extremely minute portion of alumina and a trace of oxide of iron. Its lime is pure white. The lime used now by the Florentine fresco painters is so nearly pure carbonate of lime that no appreciable quantity of any admixture can be detected. The limestone used by the painters of Genoa is also of the purest white, and is extremely good; it contains about one-third carbonate of magnesia. The Genoese frescoes, notwithstanding their vicinity to the sea, are perfectly durable. The first fresco that was executed in Genoa, according to Soprani, is still in excellent preservation; it is the Annunciation of the Virgin, in Santa Maria di Castello, painted by Justus de Alemania, or Justus of Germany, in 1451. The lime used by the fresco painters of Munich is made of the marble pebbles brought down from the Bavarian Alps by the Isar. Excellent limestone for the purpose is found also in England, on Durdham Down, in the neighbourhood of Bristol, and in other parts. Analyses of all these and other varieties are given in the Reports of the Commissioners of the Fine Arts.

Modern fresco painters recommend the lime to be kept a much longer period than Cennini and other early writers direct. If used too fresh, it blisters, and sometimes turns the colours to a brownish red; its caustic quality requires to be mitigated, but not destroyed, before it is used. On this subject Sir Charles Eastlake's Report contains several scientific observations, upon the authority of Mr. R. Phillips, from which we learn that the non-caustic state of lime is arrived at when, by exposure to the air or by other means, it is restored to the state of a carbonate or has regained its maximum of carbonic acid. If buried and kept air-tight, it cannot acquire the carbonic acid which renders it non-caustic. Time therefore has no effect on pure lime, whether slaked or unslaked, provided it be not exposed to the air or some other source of carbonic acid.

The lime used for the *intonaco* in fresco painting must, however, not be entirely carbonated, or it would not set; a certain degree of causticity is necessary—how much, however, can be learnt probably by practice only; and this is the greatest practical difficulty in the art. The picture must be executed while the *intonaco* is wet or soft; no more work therefore ought to be commenced than can be completed within the time (a few hours) that the plaster requires to harden. Numerous joints are thus necessary in a large fresco, and the judicious painter will contrive that these joints shall be identical with the inner outlines of the parts of the figures and their draperies, or any other object, so as to be no disfigurement to the work.

Cornelius recommends the following mode of preparing the lime. A pit, lined with brick, is filled with clean burnt limestones, which, on being slaked, are stirred continually until the substance is reduced to an impalpable consistence. Clean river-sand is then spread over the surface, to the depth of a foot or more, and then the whole is covered with earth so as completely to exclude the air. It is allowed to remain in this condition for at least three years: it retains its moisture for many years. It is excluded from the air, for the reasons assigned above, that it may retain its causticity, and not become entirely carbonated. But there appears to be no real necessity for keeping the lime so long buried; and river-sand should be used with great caution. Wishing to employ a ground darker than the usual white intonaco for some of the paintings he was engaged on in the new palace, Mr. Dyce procured specimens of the dark gray sand of the river Lune in Yorkshire, and "the result was encouraging." But desiring to be assured as to its chemical properties, he applied to Professor Hofmann, who, on analysing it, discovered that the dark colour was attributable to the presence of iron pyrites, and pointed out that an "intonaco deriving its tint from such a cause, when exposed to the action of the atmosphere, is likely to crumble much sooner than one in which sand free from iron pyrites is employed." But as Sir R. Murchison observed, river sands nearly always "contain impurities and oxidisable substances which would be sure to affect the intonaco." "The analysis," continues Sir Roderick, "of the old Paduan frescoes (of Giotto) shows that there was scarcely a trace of iron in the Italian mixture, which was, I dare say, made up of the purest silicious sand which could be procured with one of the crystalline limestones or pure marbles of the country, nearly all of which contain some magnesia. The sculptors may aid the painters, and the *rejectamenta* of the former may prove the best possible material for mixing up with the pure white sand, for it is highly charged with carbonic acid. Besides, by this process one half of the material would be Italian, and possibly, if not probably, the very lime used by Giotto." (Eleventh Report.) This last is a hint well worth attending to.

3. *Execution of the Fresco.*—Cornelius recommends three years' interval between the rough coating of the wall and the commencement of the actual preparation for painting, unless the lime used in the first instance be very old, when between six and twelve months will be sufficient. Before laying on the *intonaco* the prepared ground must be repeatedly wetted with rain-water or boiled water, or still better, distilled water, until it will absorb no more; then a thin moderately rough coat of plaster of sand and lime must be laid over as much of the wet surface as can be painted in one day; as soon as this coat begins to set, in about ten minutes or so, another thin coat must be laid on with a wooden trowel, somewhat fatter, that is, with more lime and less sand, or with about equal parts of lime and fine river-sand; both layers together being scarcely a quarter of an inch thick. Upon this coat the fresco is to be painted: if the surface as left by the wooden trowel is found to be too smooth, it can be made slightly rough with a dry brush. This *intonaco* will be fit to paint upon in about a quarter of an hour: it is hard enough to receive the colour as soon as it will not yield to the pressure of the finger; if too soft, the wet brush will wash up the sand. The first process in executing the picture is to pounce or trace the outline of the allotted work, from the expressly prepared cartoon, of the same size as the fresco, upon the *intonaco* with a hard point (the artist must please himself as to the method of tracing); then the painting may be commenced in thin watery washes, from the finished coloured sketch, which must be placed so as to be conveniently seen while at work; for the process of fresco-painting should be simple copying; the mere execution requires so much attention, that it is necessary for the painter to be relieved of every other consideration. After the first wash is finished, an interval of twenty or thirty minutes should be allowed for the absorption of the water before commencing the second painting, otherwise in retouching and elaborating the design the surface would be washed up and the work destroyed. While the *intonaco* is wet, a repetition of the same tint will have the effect of a darker tint, as in water-colour drawing: the retouches for strengthening and rounding should be hatched, and, where great depth or force is required, repeated hatchings are necessary. The surface must be constantly kept moist (but not wet) while painting, or the superadded colour will not unite with what is beneath; the work is finished by glazings and washings. When the portion of the picture allotted for the day's work is completed, the superfluous portions of the *intonaco* should be carefully cut away. In the next day's operation the surface must be wetted as before, and the edging of the finished piece carefully moistened with a brush. If it should be necessary to leave the work for an hour or two, it may be kept moist by pressing a wet linen cloth against it, by means of a board padded and covered with a waxed cloth; the board may be propped against the wall by a pole from the ground.

If a piece of work should be unsatisfactorily executed, or accidentally damaged, it must be entirely cut away, and the whole operation be commenced afresh. A fresco cannot safely be retouched when dry, but if retouched the vehicle should be vinegar and the white of egg; this answers well for the shadows: the lights are sometimes heightened by crayons made of pounded egg-shells. It is useless, however, to retouch a fresco in the open air, as the rain would wash all retouches away; the fresco itself is not injured by rain.

The colours used in fresco-painting are all ground and mixed in water, boiled or distilled; they are chiefly earths; no vegetable and few mineral colours can be used with safety, but there is a mode of rendering vermilion durable. The white used is exclusively lime, which has either been well washed and long kept, or, by boiling and repeated manipulations and drying, is rendered less caustic. The following colours are used by Hess, the eminent German fresco-painter:—*yellow*, all kinds of ochres, raw siena; *red*, all kinds of burnt ochres, burnt siena, oxides of iron, and lake-coloured burnt vitriol; *green*, terra-vert, or Verona green, cobalt-green, and chrome-green; *blue*, ultramarine pure and factitious, cobalt. These colours are perfectly safe; chrome-yellow and vermilion are also used, but not in every case with success. Lime destroys all animal and vegetable colours.

The tints should be carefully prepared and kept in pots, and if a great quantity of any one tint should be required in one picture, it should all be prepared at once, as it is almost impossible to match tints exactly, as they are of different degrees when wet and when dry.

The brushes are of the ordinary materials, but should be somewhat longer than those used in oil-painting. In addition to hogs'-hair tools, small pencils of otter hair in quills are used: other hairs will not resist the lime, which burns and curls them. The palette, commonly made of tin, with an edge to prevent the colours from running off, should be covered with varnish, to preserve the tin from rust.

To know when to leave off is a great art in oil-painting, but in fresco it is of the utmost importance. On this subject Hess says, "If the touches of the pencil remain wet on the surface, and are no longer sucked in instantaneously, the painter must cease to work, for henceforth the colour no longer unites with the plaster, but when dry will exhibit chalky spots. As this moment of time approaches, the absorbing power increases, the wet brush is sucked dry by mere contact with the wall, and the operation of painting becomes more difficult. It is therefore advisable to cease as soon as these indications appear. If the wall begins to show these symptoms too soon, for example in the second painting, some time may be gained by moistening the surface with a large brush, and trying to remove the crust or setting that has already begun to take place: but this remedy affords but a short respite."

Fresco-painting as thus described is sometimes termed by Italians *buon-fresco*, to distinguish it from another method which they term *fresco-secco*, dry fresco.

Fresco-secco is practised at Munich as follows, as described in Mr. Wilson's report:—The plastering of the wall having been completed as for buon-fresco, the whole is allowed to dry thoroughly. Before painting, the surface of the *intonaco* must be rubbed with pumice-stone, and on the evening of the day before the painting is to be commenced, it must be thoroughly washed with water mixed with a little lime; it must be wetted again the next morning, and it is then ready for pouncing or tracing the outline, and painting; the wall must be kept constantly moist by means of a syringe. The colours used are the same as in *buon-fresco*, and the work is very durable. All fresco painters do not trace their outlines from cartoons, but it is the safest practice, and has been adopted by all the best masters. *Fresco-secco* is a good method for decorative painting, for which it is now much employed.

4. *Cleaning and transferring Frescoes.*—Frescoes are best cleaned with bread. The mouldy appearance which sometimes shows itself can be removed with a wet sponge, unless it arise from saltpetre in the walls, in which case there is no remedy. These injuries must be provided against in the construction of the walls: the vertical progress of damp may be intercepted by covering one of the lower courses of bricks or stones with sheet lead, which must be protected on each side by a coat of pitch; the wall may be then continued as usual. Frescoes may be safely washed with a soft sponge and water; vinegar and wine may likewise be used with safety; even frescoes that have been whitewashed over can be washed clean. The frescoes by Raffaelle, in the Stanze of the Vatican, though covered with nearly two centuries of dirt, were washed with wine by Carlo Maratti.

As many valuable frescoes, if left in their original localities, must have inevitably perished, through the bad construction of the walls, unfit situations, or from other causes, the invention of some mode of removing them from their objectionable situations became an object of great interest, and several very ingenious methods of transferring frescoes from walls have been devised, and often practised with success. Mr. Ludwig Gruner removed and transferred to canvas, in 1829, at Brescia, some frescoes by Lattanzio Gambara, in the convent of St. Eufemia, in the following manner:—the first process was to clean the wall perfectly; then to pass a strong glue over the surface, and by this means to fasten a sheet of fine calico upon it. The calico, being made fast by the glue to the irregularities of the wall, was itself covered with glue, and some strong linen glued over it. "In this state heat was applied, which caused the glue, even on the fresco, to sweat through the cloths, and to incorporate the whole. After this a third layer of strong cloth was applied on a new coat of glue. The whole remained in this state two or three days (the time required may vary according to the heat of the weather). The superfluous cloth extending beyond the painting was now cut off so as to leave a sharp edge: the operation of stripping or rolling off the cloths began at the corners above and below, till at last the mere weight of the cloth and what adhered to it assisted to detach the whole, and the wall behind appeared white, while every particle of colour remained attached to the cloth. To transfer the painting again to cloth, a stronger glue is used, which resists moisture, it being necessary to detach the cloths first used, by tepid water, after the back of the painting is fastened to its new bed."

Some frescoes by Paul Veronese, in the Morosini villa, near Castel Franco, were transferred by Count Balbi of Venice. Cloth was fastened to the wall by means of paste made of beer and flour, and rivetted to the irregularities of the surface by means of a hammer composed of bristles.

Cicognara, *Del Distacco dèlle Pitture a Fresco*, 1825, in 'Antologia di Firenze,' vol. xviii. num. 52; Baruffaldi, *Vita di Antonio Contri, Pittore e Rilevatore di Pitture dal Muro*, Venice, 1834; Förster, *Beiträge zur neuern Kunstgeschichte*, Leipzig, 1835; Cenni, *Sopra diverse Pitture staccate dal Muro e trasportate su Tela*, &c., Bologna, 1840; Eastlake, *Materials for a History of Oil Painting*, 1847, (chap. vi.); *Contributions to the Literature of the Fine Arts*; Mrs. Merrifield, *Original Treatises dating from the* 12th to 18th *centuries on the Arts of Painting*, 2 vols. 1849; Taylor, *Manual of Fresco and Encaustic Painting*, 1843; the *Appendices to the Reports of the Commissioners on the Fine Arts*, from the 2nd Report published in 1842, to the 11th published in 1858, which contain much important matter connected with fresco-painting, including many details on subjects to which there is not space in this article even to allude.

FRET, in musical instruments of the stringed kind, is a wire fixed in the neck, for the purpose of marking the exact part of the finger-board to be pressed for the purpose of producing certain sounds. Frets are now never applied to any instruments except guitars, lutes, &c.

FRIARS, from the French *frères*, a term in strictness meaning the brethren of a community, but more particularly applied to a new order of religious persons, who mostly sprang up at the beginning of the 13th century, and were encouraged in the hope of restoring respect to the monastic institution, the ample endowments of which had led it to degenerate from its primitive austerity, and yield to luxury and indulgence.

The friars consisted of Dominicans, Franciscans, Carthusians, Cistercians, Trinitarians or Maturines, Crossed or Crutched Friars, Austin Friars, and Bonhommes or Good Men. These last were brought into England by Edmund, earl of Cornwall, in 1283, and a colony of them was placed at Ashridge in Buckinghamshire. The Capuchins and Observants were distinctions of the Franciscan Friars.

Accounts of the principal orders will be found under their respective heads.

FRICTION. The rubbing together of two substances, in the course of which action (in mechanical operations) a resistance is developed to the motion of those substances. The resistance of friction is produced by the asperities, or unevenness, of the rubbing surfaces; for however perfect the polish of those surfaces may be, there are always irregularities of height, or of hardness, in the molecules of the respective bodies of a nature to allow some of the particles of the upper one to force themselves into the depressions, or softer particles of the lower, from whence they cannot be removed without the exercise of a force opposed to the continuance of motion. At the present day it is customary to consider Friction under two heads, the *Friction of sliding*, or that which is produced when the moving body passes constantly over the same part of the fixed surface, or *vice versâ*; and the *Friction of rolling*, or that which is produced when the parts of the surfaces of contact are constantly changing their relative positions.

Amontons, Bulfinger, Parent, Euler and Coulomb, were amongst the earliest writers on physics who treated the subject of Friction, and their researches have been confirmed and developed by the labours of Fergusson, Vince, Navier, Morin, &c. The laws deduced by these observers may be thus briefly stated.

1. Friction is proportional to the normal pressure which the surfaces of contact exercise on one another, but it varies according to the nature and the state of the surfaces of contact, and is independent of the velocity of movement, or of the extent of the surfaces. The above law is, however, limited in this sense, namely, that when the pressure exceeds a certain point, the surfaces are as it were driven into one another, and the friction of the bodies in motion increases without any apparent rule; it becomes in fact abrasion.

2. When bodies have been for some time in contact, especially if they should be of a compressible nature, the sliding friction will be found to be greater at the commencement of motion than at a subsequent period. A slight blow in the direction of the intended motion will produce a sufficient movement to obviate the effects of this temporary increase of resistance. The coefficient of friction is the term applied to the force which it is necessary to exert in order to overcome the resistance directly opposed to motion; and, as it is proportionate to the normal pressure exercised by the two surfaces in contact, it is expressed by the simple formula $f=\frac{F}{P}$, in which f= the coefficient required, F= the resistance ascertained experimentally; and P= the pressure. Elaborate tables of the coefficients of sliding and rolling friction have been drawn up by Morin; and others are quoted by Poncelet in his 'Introduction à la Mécanique Industrielle,' see also Claudel, 'Formules à l'usage des Ingénieurs,' &c.

3. The interposition of an unguent of any description modifies these laws in a very remarkable manner, so that it is necessary to calculate upon a particular coefficient of friction dependent upon the nature and state of the unguent, and upon its mode of supply, whenever any of this class of materials are used.

4. The friction of cylinders rolling upon a horizontal plane is in the direct ratio of their weights, and in the inverse ratio of their diameters.

5. In all cases in which solid bodies rest upon one another, there is an inclination of the surfaces of contact at which the bodies are susceptible of motion by the mere effect of gravity; and it is of the utmost importance in all the operations of applied mechanics to ascertain the precise value of this *angle of inclination*, or, as it is sometimes called, of this *limiting angle of resistance*. Morin's tables contain a series of practical observations on this subject; they have been translated in Moseley's admirable work, 'The Mechanical Principles of Engineering and Architecture.' The thrust of earthworks upon retaining walls is a special illustration of this problem, which will be discussed under RETAINING WALLS.

6. In practical mechanics, also, the effects of friction are in some cases modified by the resistance offered by the rigidity of the materials in motion; as, for instance, in the case of cords working over pulleys, or of bands working upon driving wheels. The particular laws of this class of actions will be discussed under RIGIDITY OF CORDS; and for the present it may suffice to say that the increase of resistance occasioned by the cord or band may be represented by a formula of two terms, one of which is a constant quantity, and the other the product of a constant quantity, or factor of the resistance divided by the resistance itself: so long, at least, as the same cord only is concerned. For different cords, the constants vary, within certain limits, as the squares of the diameters or of the circumferences of the cords, in respect to new cords, wet or dry; in respect to old cords, they vary nearly as the $\frac{3}{2}$ power of the diameters, or of the circumferences. The rigidity of cords only acts to increase the resistance in the portions of their length where they wind upon the pulleys.

Friction is considered, and sometimes practically resorted to, as a source of heat, for the inhabitants of the South Sea Islands obtain fire by rubbing two pieces of dry wood violently against each other. The heat developed by the friction of machinery in motion is one of the most serious causes of its deterioration; and it is on this account, nearly as much as upon account of the motive power lost through the resistance of friction when no lubricating materials are used, that it is necessary to provide for the continuous supply of fresh and cool lubricators. It may occasionally happen that the pressure, or weight, of the moving body may force out the greases ordinarily used from between the bearing surfaces, in which cases, heating, friction, or even abrasion, may ensue. It is therefore important to proportion the area of the bearing surfaces to the pressure in such wise as to prevent its attaining this limit; and, under any circumstances, to use the most fluid lubricators possible, as they will most easily be forced into the inequalities of the surfaces. Grease, for instance, is a better lubricator than water: oil than grease; and of oils it would appear that the mineral ones are better adapted to this use than either the animal or the vegetable ones.

FRIDAY. [Week.]

FRIENDLY SOCIETIES. These institutions, which, if founded upon correct principles and prudently conducted, are beneficial both to their members and to the community at large, are of very ancient origin. Mr. Turner, in his 'History of the Anglo-Saxons,' notices them in these words: "The guilds or social corporations of the Anglo-Saxons seem on the whole to have been friendly associations made for mutual aid and contribution, to meet the pecuniary exigencies which were perpetually arising from burials, legal exactions, penal mulcts, and other payments or compensations." (See also Herbert's 'History of the Twelve Great Livery Companies,' vol. i., p. 1.)

In 1773 a bill was brought into the House of Commons for "the better support of poor persons in certain circumstances, by enabling parishes to grant them annuities for lives upon purchase, and under certain restrictions." The bill passed the Commons, but was rejected by the Lords. A bill with a similar object met with the like fate in 1780. A bill introduced in 1793 by the late Mr. George Rose passed into a law (33 George III. c. 54), which is known by his name, and was extensively acted upon. This act recited "that the protection and encouragement of friendly societies in this kingdom, for securing, by voluntary subscription of the members thereof, separate funds for the mutual relief and maintenance of the said members in sickness, old age, and infirmity, is likely to be attended with very beneficial effects," and it authorised persons to form themselves into a society of good fellowship, for the purpose of raising funds, by contributions or subscriptions, for the mutual relief and maintenance of the members in old age, sickness, and infirmity, or for the relief of the widows and children of deceased members. A committee of members was authorised to frame regulations for the government of the society, which regulations, after being approved by the majority of the subscribers, were to be exhibited to the justices in quarter-sessions, and if not repugnant to the laws of the realm, and conformable to the true intent and meaning of the act, were to be confirmed and made binding upon the subscribers.

Among other provisions, it was allowed to impose reasonable fines upon such members as should offend against the regulations; such fines to be applied to the general benefit of the society. By this act it was declared unlawful "to dissolve or determine any such society, so long as the intents or purposes declared by the society remain to be carried into effect, without the consent and approbation of five-sixths of the then existing members, and also of all persons then receiving or entitled to receive relief from the society on account of sickness, age, or infirmity." Societies thus constituted were relieved from the payment of certain stamp-duties, and were empowered to proceed for the recovery of moneys, or for legal redress in certain cases, by summary process, without being liable to the payment of fees to any officer of the court; and to aid them, the court was required to assign counsel to carry on the suit without fee or reward.

In 1795 an act was passed which extended the privileges of Mr. Rose's act to other "benevolent and charitable institutions and societies formed in this kingdom for the purpose of relieving widows, orphans, and families of the clergy and others in distressed circumstances." Several other acts were passed between 1795 and 1817 affecting the proceedings of these societies, but not in any matter of importance. In the last-mentioned year the "Savings' Bank Act" was passed, and under its provisions the officers of friendly societies were allowed to deposit their funds in any savings' bank, by which means they got security for their property and a higher rate of interest than they could otherwise obtain. This act has been of essential benefit to these associations. Another law, making provisions for the further protection and encouragement of friendly societies, and for preventing frauds and abuses in their management, was passed in 1819; but as this and all other acts previously passed with the same object were repealed and superseded by the act of 1829 (10 Geo. IV. c. 56), which, with two acts passed in 1832 and 1834 (2 Wm. IV. c. 37, and 4 & 5 Wm. IV. c. 40), contain the law as it now stands for the regulation of friendly societies, it is unnecessary to detail here the alterations effected in 1819.

In the years 1825 and 1827 select committees were appointed by the House of Commons to consider the laws of friendly societies. The reports made by these committees have thrown considerable light upon the subject, and prepared the way for the enactment of 1829, already mentioned, which, with the subsequent acts of 1832 and 1834, we now proceed to analyse.

The law of 1829 (10 Geo. IV. c. 56), in the first place, authorises anew the establishment of societies within the United Kingdom, for raising funds for the mutual relief and maintenance of the members. The members of such societies are to meet together to make such rules for the government of the same as shall not be contrary to the intent of the act nor repugnant to the laws of the realm, and to impose such reasonable fines upon the members who offend against any of such rules as may be necessary for enforcing them; and these rules, which must be passed by a majority of the members present, may be altered and amended by the same authority.

But before these original or amended rules shall be confirmed by the justices of the county at the general quarter-sessions, they must have inserted in them a declaration of the purposes for which the society is established, and the uses to which its funds shall be applied, stating in what shares and proportions, and under what circumstances any member of the society or other person shall be entitled to the same; and further, it is required that the rules so passed "shall be submitted, in England and Wales and Berwick-upon-Tweed, to the barrister-at-law for the time being appointed to certify the rules of savings' banks; in Scotland, to the lord-advocate or any of his deputies; and in Ireland, to such barrister as may be appointed by her Majesty's attorney-general in Ireland, for the purpose of ascertaining whether such rules are in conformity to law and to the provisions of this act." The officers here mentioned are respectively to settle such rules, and make them conformable to law and to this act of parliament, and to give a certificate of this regulation having been complied with. The rules so certified are then to be deposited with the clerk of the peace for the county wherein the society is formed, and by him to be laid before the justices at quarter-sessions, who are required to confirm the same, after which the rules and certificate are to be filed with the rolls of the sessions of the peace, and a certificate of such enrolment, signed by the clerk of the peace, is to be sent to the society. If the barrister or other officer above mentioned shall refuse to certify the rules offered for his approval, the society is allowed to submit the same to the court of quarter-sessions, together with the reasons assigned for refusal, when the justices may, if they see fit, confirm the rules, notwithstanding the disapproval of the revising officer.

Before these directions are complied with, no society is entitled to enjoy any of the privileges or advantages communicated by the act; but when the rules shall have been enrolled, and until they shall have been altered and the like confirmation shall have attended such alteration, they shall be binding upon the members of the society, and a certified copy of them shall be received in evidence in all cases. The treasurer of each society must give bond to the clerk of the peace for the county, with two sufficient sureties, for the faithful performance of his trust, and must, on the demand of the society, render his accounts and assign over the funds of the society at the demand of a meeting of the members. The property of the society is to be vested in the treasurer or trustees of the society, who may bring and defend actions, "criminal as well as civil, in law or in equity," concerning the property, right, or claim of the society, provided they shall be authorised to do so by the vote of a majority at a meeting of the members.

In case any person shall die intestate whose representatives shall be entitled on his account to receive any sum from the funds of the society not exceeding 20*l.*, the treasurer or trustees may pay the money to the persons entitled to receive the property of the deceased, without its being necessary to take out letters of administration.

It is not lawful to dissolve any friendly society, so long as any of the purposes declared in its rules remain to be carried into effect, "without obtaining the votes of consent of five-sixths *in value* of the then existing members, and also the consent of all persons then receiving or then entitled to receive relief from such society; and for the purpose of ascertaining the votes of such five-sixths in value, every member shall be entitled to one vote, and an additional vote for every five years that he may have been a member, provided that no one member shall have more than five votes in the whole."

The rules of the society are to contain a declaration whether, in the event of any dispute or difference arising between the society and any one or more of its members, the matter shall be referred to the decision of a justice of the peace or of arbitrators; if to the latter, the arbitrators must be chosen or elected in sufficient number at the first meeting of the society which shall be held after the enrolment of its rules; they must not be in any way interested in the funds of the society; and whenever the necessity for their employment shall arise, a certain number, not exceeding three, are to be chosen by ballot from among the arbitrators for the settlement of the dispute, and justices are empowered to enforce compliance with the decision of the arbitrators. If the rules of the society direct the application, in cases of disputes, to justices of the peace, any justice is empowered to summon the person against whom complaint is made, and any two justices may hear and determine the matter, their sentence or order being final and conclusive. Minors, if they act with the consent of parents or guardians, may become members of friendly societies, having authority to act for themselves on the one hand, and being held legally responsible for their acts on the other.

A statement, attested by two auditors of the funds belonging to each society, shall be made annually to its members, every one of whom may receive a copy of the statement on payment of a sum not exceeding sixpence.

Every friendly society enrolled under this act is obliged, within three months after the expiration of every five years, to transmit a return of the rate of sickness and mortality, according to the experience of the society during the preceding five years, such returns to be made in a prescribed form to insure uniformity. These returns are directed by 4 & 5 Will. IV. c. 40, to be addressed to the barrister appointed to certify the rules of friendly societies, London.

The provisions of the act of 1834 (4 & 5 Will. IV. c. 40) are for the most part confined to matters of regulation which it is not necessary to notice here.

The following are among the benefits derived from a Friendly Society being enrolled under the Geo. IV. c. 56, as amended by the 4 & 5 Wm. IV. c. 40:—1. The rules are binding, and may be legally enforced; 2. Protection is given to the members, wives and children, &c., in enforcing their just claims, and against any fraudulent dissolution of the society; 3. The property of the society is declared to be vested in the trustee or treasurer for the time being; 4. The trustee or treasurer may, with respect to property of society, sue and be sued in his own name; 5. Fraud committed with respect to property of society is punishable by justices; 6, Court of Exchequer may compel transfer of stock, &c., if officer of society abscond or refuse to transfer, &c.; 7. Application may be made to Court of Exchequer by petition, free from payment of court or counsel's fees, &c.; 8. Disputes settled by reference to justices or arbitrators—order of justices or award of arbitrators final; 9. Power to invest their funds to any amount in savings' bank; 10. Power to invest their funds with the commissioners for the reduction of the national debt, and to receive interest at the rate of 3*l.* 0*s.* 10*d.* per cent.; 11. Priority of payment of debts, in case officer, &c., of society become bankrupt, insolvent, has an execution, &c., against his property, or dies; 12. In case of death of members, payment may be made of sum not exceeding 20*l.*, without the expense, &c., of obtaining letters of administration; 13. Members are allowed to be witnesses in all proceedings, criminal or civil, respecting property of society; 14. Exemption of all documents, &c., from stamp-duty.

Societies thus constituted and privileged must be acknowledged to be a great improvement upon the old benefit clubs. Before these societies were regulated by statute, temptation was held out to obtain members by the smallness of the contributions, which proved in the course of years wholly inadequate to answer the demands that were then sure to arise, although the income of the society had at first, while the members continued young, been sufficient for the purpose. The mischief thus fell upon them when they had become old and infirm, and had no means of relieving themselves from it; this evil is now prevented by the compulsory adoption of tables prescribing such rates of contributions and allowances as experience has demonstrated to be sufficient and equitable.

By the 10 Geo. IV. c. 56 (as amended by the 4 & 5 Wm. IV. c. 40), friendly societies may be formed for providing relief to members, their wives, children, relations, or nominees, in sickness, infancy, advanced age, widowhood, or other natural state of contingency whereof the occurrence is susceptible of calculation by way of average, or for any other purpose which is not illegal; the rules therefore may now provide for relief in case of loss by fire, or by shipwreck; substitutes if drawn for the militia; a weekly allowance if reduced to a workhouse, imprisoned for debt, and for payment towards the expenses of the feast, &c. &c.; but, for all such purposes, the contributions must be kept separate and distinct from the payments which may be required, on account of relief in case of sickness, infancy, advanced age, widowhood, or other natural state of contingency, susceptible of calculation by way of average; or the charges may be defrayed at the time by extra subscription of the members. The money payable on the death of a member may be received by any person nominated by such member, and is not confined to his wife, child, or relation.

It is unnecessary to give the tables of contributions required from members of friendly societies, in order to insure to their members the benefits of such institutions, as every information respecting the establishment of friendly societies may be obtained, free of expense, on application, through a post-paid letter, to the "Barrister appointed to certify the Rules of Friendly Societies, London."

On the 20th of November, 1858, the number of friendly societies which had direct accounts with the commissioners for reduction of the national debt was 571, and the amount of their deposits was 980,354*l.* There were besides, at the same date, 9994 friendly societies, which had the sum of 1,562,784*l.* invested in savings' banks.

Since the passing of the Act of 1793 to the end of 1858, there had been enrolled and certified 28,550 friendly societies, of which 6830 had then ceased to exist, and several more ceased in 1859, chiefly from the decreased number of members, and from their growing age without the admission of younger members. A large number of these societies exist, also, of which the rules are not certified, nor are they enrolled, and the parliamentary report expresses its belief in the unsoundness of many of them, owing to the insufficiency of the contributions.

FRIEZE. [Column; Greek Architecture.]

FRIGATE. [Ship.]

FRIGIDARIUM. [Bath.]

FRISIANS, a people of Germany, who formed part of the nation of the Ingævones. Their name has been by some derived from the low German word "fresen," to shake or tremble, in allusion to the nature of their country, the soil of which is an unstable or shaking moor. They were divided into Frisii Minores, who inhabited the lands north of the island of the Batavi—the present provinces of Oberyssel, Gelders, and Utrecht, and the greater part of the province of Holland, inclusive of the Zuidersee, which at that time was mostly dry land; and the Frisii Majores, who inhabited the land between the Yssel, Ems, and the country of the Bructeri—that is, the present provinces of West Friesland and Groningen. The old Rhine separated them from the Batavi, and the Ems from the Chauci. According to Tacitus ('Ann.' ii. c. 24) they were the most steadfast allies whom the Romans possessed in this quarter; they aided Drusus and Germanicus in their campaigns against the Cherusci, and saved the Roman fleet from destruction at the mouth of the Ems. But this state of amity was broken off upon the Romans making an attempt to treat them as subjects; they thenceforward became declared enemies of Rome, and razed, with one exception, all her strongholds in these parts, having in the 28th year A.D., when Olennius was the Roman lieutenant, turned upon the Romans, slain about 900 of them near the woods of Baduhenna, and freed themselves from their dominion. (Tacit. 'Ann.' iv. c. 72, 73.) Corbulo, the Roman general under Claudius, A.D. 47, reduced them to obedience, and Nero drove them out of some districts on this side of the Zuidersee, which they had invaded. (Tacit. 'Ann.' xiii. c. 54.) From this period until the 4th and 5th centuries, when they appear as members of the great confederacy of the Saxons, no mention of them occurs. We find them at this time holding the sea-coasts from the Schelde to the Elbe and Eyder, whence it has been conjectured that a variety of tribes were then comprehended under the name of Frisians. They now passed over into Britain, in company with the Angles and Saxons, and aided them in its conquest. Under the emperor Julian they made themselves masters and retained possession of the island of the Batavi, on which spot they were sorely humbled by Pepin, major-domo of the Franks, who put Radbod their king to flight, and wrested the whole of their western lands from them as far as the mouths of the Rhine. Poppo, Radbod's successor, made a fruitless attempt to recover the lost territory, and was driven back by Charles Martel. Charlemagne hereupon brought the eastern dominions of the Frisians under subjection, and appointed his own dukes over them, whose office subsequently merged into that of chieftain (häuptling). The result of continued struggles for the mastery between these chieftains, who called themselves counts, was, that count Edzard prevailed, and established himself in that part called East Friesland, in 1458. In 1657, count Enno acknowledged it as a fief of the empire under the emperor Ferdinand, and was raised by him to the dignity of a sovereign prince; but both his power and that of his descendants was jealously limited by the national states. The last prince died in 1744, and by virtue of an imperial grant in 1690, Prussia took possession of East Friesland. It was wrested from her in 1808, and transferred to Holland; in 1810 it became a province of the French empire; in 1813 Prussia recovered it, and in 1815 she ceded it to Hanover.

The western part of the Frisian territory, or West Friesland, is a province of the kingdom of Holland.

The ancient Frisians resembled the Germans in their habits and mode of living, and according to Tacitus, the only tribute they could afford to pay the Romans consisted of skins. They were governed by two princes, whose authority was extremely confined. Their descendants are settled among the small islands on the western coast of the duchy of Schleswig, and preserve not only the name of Frisians, but many vestiges of their customs and dress.

FRIT. [Glass.]

FRONDE, the name of a political faction in France during the minority of Louis XIV., which was hostile to the prime minister, Cardinal Mazarin, and to the queen regent, who supported him. In consequence of some disputes between the parliament of Paris and the court, the cardinal ordered the arrest of the president and of one of the councillors of the parliament in August, 1648, and this act was the signal of a civil war. The party opposed to the court affected to declare themselves not against the queen's government, but only against the cardinal, whom they attacked by accusations and lampoons, from which they derived the name of "Frondeurs," "censurers," or "jeerers." They had for leaders the Duke of Beaufort, the Duke de Némours, the Prince of Conti, the Duke de Vendôme, the Abbé de Retz (afterwards cardinal), Marshal Turenne, and other men of the first rank, as well as ladies,—among others the Duchesse de Longueville, who was a most conspicuous and violent partisan. The people of Paris took part with the Frondeurs; they drew chains across the streets, attacked the troops, and obliged the queen to liberate the two members of the parliament. This was called "the day of the barricades." A kind of truce took place; but the parliament continued refractory, the court hostile, and the people tumultuous; and the queen regent, seeing herself obliged, in January, 1649, to remove from Paris with her son to St. Germain, charged the Duke of Orleans and the Prince of Condé with the task of reducing Paris by blockade. Louis XIV. was then little more than ten years of age, but he never forgot the humiliation of being obliged to leave his capital, and this was the first cause of his subsequent hostility towards the parliament. That court, in the mean time, exercised sovereign power in the capital, levied troops, and passed a resolution declaring Cardinal Mazarin a public enemy, and outlawing him. ('Histoire du Parlement de Paris,' Amsterdam, 1769.) After some fighting in the neighbourhood of Paris a truce was made, a general amnesty was granted by the queen, the parliament retained full liberty to assemble, and the queen, king, and minister re-entered Paris in the month of August. The disturbances, however, continued in the provinces, especially in Provence and Guienne, where the local parliaments resisted the authority of the respective royal governors. In 1650 the queen, hurt by the overbearing tone and high pretensions of the Prince of Condé, made her peace with some of the Frondeur leaders, and caused the princes of Condé and Conti to be arrested. Upon this, the Duchess of Longueville, Marshal Turenne, and others, raised the standard of revolt in the provinces, and were joined by the Spaniards from Flanders. The war, which now assumed a more serious aspect, continued till 1653, when Turenne made his peace with the court, and Mazarin returned in triumph to Paris. [CONDÉ, LOUIS DE in BIOG. DIV.]

FRONTISPIECE, the front or principal face of a building; the front view; anything seen in or at the front, Johnson says "id quod in fronte conspicitur." Hence, by a figure, we call the engraved title of a book, or the print which faces the title-page, a frontispiece.

FROST. [FREEZING.]

FRUCTOSE. [SUGAR.]

FRUIT, in botanical language, signifies that part of a plant in which the seed is lodged, whatever its size, colour, or texture may be, so that the seed-like grain of a sage, the grain of corn, the nut of a chestnut, the dry capsule of a lilac bush, are as much fruits as those of a peach, an apple, or a pine-apple. In the ordinary acceptation of the term however the word fruit is exclusively applied to seed cases which are eatable, and generally to such as require no preparation to render them fit for food.

The eatable fruits known in this climate are of so much importance to the comfort as well as luxury of society, that without entering much into details we shall here introduce some general observations, which will inform our readers what are the kinds most deserving of cultivation in select or confined gardens. In doing this we have the advantage of reproducing in a condensed form the important results of the laborious and costly investigations conducted for so many years in the garden of the Horticultural Society of London at Turnham Green. These have already been made known to the public in the second edition of the 'Catalogue of Fruits,' cultivated in that establishment; and our only task is to make a judicious selection from the thousands of varieties included in the Society's list.

The species of cultivated fruits are far from numerous; and most of those of the temperate regions have been introduced, at one period or another, into Britain. The genera from which these have sprung are comparatively few, and chiefly included in the natural orders Rosaceæ, Vitaceæ, Urticaceæ, and Grossulaceæ. To the first of these are to be referred the genera producing the species called apples, pears, plums, cherries, apricots, peaches, and nectarines, quinces, medlars, raspberries, and strawberries; to the second, the vine; to the third, the fig and mulberry; and to the fourth, the gooseberries and currants. Moreover there are chestnuts and filberts belonging to Corylaceæ; walnuts to Juglandaceæ, and the melon and pine-apple respectively to Cucurbitaceæ and Bromeliaceæ.

In this place we shall briefly enumerate what may be considered the most valuable varieties of each as objects of cultivation.

Apples are the most numerous class in cultivation. It has been conjectured that they were brought to this country by the Romans; but it is doubtful whether the varieties then introduced would succeed in this climate, presuming on the fact that the *Malo di Carlo*, well known as being so exceedingly beautiful and delicious in the North of Italy, has, in one of our finest English summers, proved pale and insipid, and that the apples of the South of Europe are generally worthless in England. A hardier breed, it is more than probable, was introduced by the Normans, especially of such as were suited for the manufacture of cider.

Apples are usually divided into three principal sorts, according as they are fitted for dessert, for kitchen use, or for cider. For dessert, the following are early varieties: Early Red Margaret, Early Harvest, Oslin, Kerry Pippin, and Summer Golden Pippin. In succession to these, the Wormsley Pippin, King of the Pippins, Golden Reinette, Ribston Pippin, Court of Wick, Pearson's Plate (a remarkably handsome dessert apple), Golden Harvey (one of the very highest excellence), Hughes's Golden Pippin, Herefordshire Pearmain, Lamb Abbey Pearmain, Court Pendu plat (which blossoms late, thereby escaping the spring frosts), Reinette du Canada, Old Nonpareil, and Scarlet Nonpareil. For early kitchen use: Dutch Codlin, Keswick Codlin, Hawthornden, Nonesuch, which last deserves particular notice on account of its beautiful transparency when made into apple jelly, for which purpose it is the best sort known. For winter and spring use, from many excellent varieties, the following are selected: Blenheim Pippin (which may be also used at dessert), Dumelow's Seedling, Bedfordshire Foundling, Alfriston, Gloria Mundi, Royal Russet, Brabant Bellefleur, Northern Greening, Norfolk Beaufin (from which the "Beaufins," or "Beefins," so generally to be seen in the London shops, are prepared), and French Crab, which will keep above a year. For cider, Siberian Bitter-Sweet, Foxley, Red Streak, Fox Whelp, Golden Harvey, Coccagee, Hagloe Crab, and Cooper's Red Streak, are amongst the most celebrated.

Of the varieties of *Pears*, few, till lately, have originated in this country; most of the kinds in former cultivation were from France, but they generally required the protection of walls. The greater intercourse with the Continent consequent upon the establishment of peace in 1815 led to the introduction of a number of new and hardy varieties of this fruit from Belgium, where its cultivation and improvement had been, and still are, attended to with great assiduity. These new varieties, with some of equal merit, and even superior hardiness, raised at Downton Castle, in Herefordshire, now compose the principal part of the most select lists, and are at the same time rapidly excluding the older French varieties from cultivation.

Pears are divided into three classes—dessert, kitchen, and perry. The following are amongst the finest. For dessert: Citron des Carmes, Jargonelle (which requires a wall), Summer St. Germain, Ambrosia, Fondante d'Automne, White Doyenné (if grown as an open standard), Seckle, Louise Bonne (of Jersey), Marie Louise, Beurré Bosc, Gansel's Bergamot (which also requires a wall), Duchesse d'Angoulême, Beurré Diel, Nelis d'Hiver, Althorp Crassane, Winter Crassane, Napoleon, Glout Morceau, Passe Colmar, Knight's Monarch, Neplus Meuris, Easter Beurré, Beurré Rance. These are enumerated in their order of becoming fit for use. For kitchen use: Bezi d'Heri (which is excellent for stewing, and very free from grittiness), Bequêne Musque, Spanish Bon Chrétien, Double de Guerre, Catillac, Uvedale's St. Germain. For perry: Oldfield, Barland, Longland, Teinton Squash.

The best varieties of *Plums* for the dessert are, the Green Gage, Washington, Reine Claude, Violette, Drap d'Or, Kirke's, Coe's Golden Drop, Blue Imperatrice. For kitchen use: Orleans, White Magnum Bonum, Shropshire Damson, which last is excellent for preserving, as are also the St. Catharine, Coe's Golden Drop, Green Gage, and Quetsche; the latter is the sort of which the German Prunes of the shops are made, by slow and repeated drying in an oven.

Cherries, it is said, were first cultivated in this country at Sittingbourn, in Kent, where they are supposed to have been introduced about the time of Henry VIII. That county is still famous for a sort called the Kentish Cherry, identical with some of the varieties of the Montmorency cherries of the French. They are round, bright red, and acid, and much used for pies. They have also the peculiar property of the stalk adhering so firmly to the stone that the latter may be drawn out without breaking the skin, except at the base. The fruit is then dried in hair sieves in the sun, or otherwise placed in a gently heated oven; the cherries will then keep for a year, and have the appearance of raisins. The best cherries for dessert are the Elton, Downton, May Duke, Royal Duke, Knight's Early Black, Early Purple Guigne, Bigarreau, Florence. For preserving, the Kentish and Morello are best.

Apricots in cultivation are of few varieties compared with any of the preceding kinds of fruits, and of those the most useful are the following: Large Early, Breda, Moorpark, Royal, and Turkey. The Breda is the best for standards; and when the season is favourable, the fruit on such, although smaller than that grown against a wall, is, notwithstanding, higher flavoured. A variety called the *Musch-Musch* may be noticed, although not recommended for cultivation in this climate. It is the sort grown in the oases in Upper Egypt, where it produces in great abundance, the fruit being dried, and in this state forming an article of commerce for exportation. The apricot blossoms earlier than any other fruit-tree cultivated in this country: hence, most probably, it was called Precocia among the Romans, a corruption of which name is traceable in the modern one of apricot. In consequence of the tree blossoming so early, its blossoms, particularly in the case of young trees, are extremely liable to drop off in setting. This is not to be wondered at, when it is considered that the ground is frequently at the time (March) in as cold a state as at any period of the whole season, neither the sun's heat nor the warm rains having reached so far below the surface as to warm the soil in contact with the roots; and thus, whilst the latter are in a medium perhaps a little above freezing, the tops, exposed to a bright sun against a wall, are at that period of the season occasionally in a temperature as high as 90° or 100° Fahr. The injurious effects of this disparity must be sufficiently obvious to every one, and the only remedy to be adopted is to have a very complete drainage below the roots, and the whole soil of the border, not retentive, but of a pervious nature. If it could also be kept perfectly dry previous to the commencement of vegetation, and then only allowed to receive the rain when warm, avoiding the cooling effects of melting snow and hail, the tree would thus be placed under circumstances comparatively more natural.

Peaches and *Nectarines* require the aid of a wall to bring them to perfection in this climate; and in the more northern counties of Britain the protection of glass is also requisite. They likewise rank among the kinds of fruits which are considered of sufficient value to be forced. A selection of the best varieties of peaches is as follows: Noblesse, Red Magdalen, Royal George, Grosse Mignonne, Belle Garde, Late Admirable. The two very best nectarines are the Elruge, which has little or no red at the stone; and the Violette Hâtive, the flesh of which is rayed with red near the stone: this serves as a principal distinction between these two varieties. For the sake of variety, the Pitmaston Orange and the White Nectarine may also beincluded. A selection of peaches for forcing may consist of the Bellegarde, Noblesse, Grosse Mignonne, Royal George, Royal Charlotte, and Barrington. Nectarines for the same purpose are the Elruge and Violette Hâtive.

The best variety of *Quinces* is the common one. The Portugal quince is distinct; but its fruit does not ripen so well in this climate as the common quince. Its wood, however, swells more in conformity with that of the pear, and it therefore is preferable as a stock for pears.

The principal varieties of the *Medlar* are the Large or Dutch, the Upright or Nottingham, and the Stoneless. The first is esteemed for its size, and sometimes for the form of the tree, on account of the rustic crooked appearance which it assumes: the second is of better quality as regards flavour; and the third is small without stones or seeds, and keeps longer than the others.

Raspberries, compared with many of the fruits mentioned above, differ little in their character as cultivated varieties from that of the botanical species *Rubus idæus*, from which they have arisen. For instance, the difference between the wild sloe and the green gage is very great; whereas the wild raspberry growing in the woods differs only slightly in flavour, and not widely in size and form, from those cultivated in gardens. Good varieties are the Red Antwerp, Yellow ditto, Barnet, Cornish, and Red Globe.

Strawberries are now considerably reduced in regard to the number of varieties in cultivation. By the introduction of "Keen's Seedling," the very coarse sorts have been mostly banished even from the streets of London; this variety having proved the best of all for the market, combining very good flavour with the properties of being of a large size and very prolific. Other varieties deserving cultivation are the Grove End Scarlet, Roseberry, American Scarlet, and, where wanted for confectionary, the Old Scarlet, which retains a fine colour; Downton, Elton, Old Pine, Prolific or Conical Hautbois, and the Large Flat ditto. The alpine and wood strawberries require to be occasionally renewed from seeds; the best varieties are the Red Alpine and the White Alpine. Keen's Seedling, Roseberry, and Grove End Scarlet, are proper for forcing.

Grapes are brought to high perfection in this country, by the aid of hothouses; in favourable situations some kinds ripen pretty well, even on walls in good seasons: but open vineyard culture is not practised to any extent in England at the present time, nor is it likely ever to become profitable. Varieties of wine grapes therefore need not be noticed here, farther than by stating that they are very numerous; many of them form small compact bunches like the "Miller's Burgundy," which is indeed one of them, and is the sort of black cluster grape with woolly, mealy leaves, commonly seen on the walls of houses near London. The following are suitable for a vinery:—Black Frontignan, Black Prince, Black Hamburg. West's St. Peter's, Black Morocco, Red Frontignan, White ditto, Grizzly ditto, Royal Muscadine, Chasselas Musqué, White Muscat of Alexandria; the last requires a strong heat. For walls, perhaps none fruits better, or forms a handsomer bunch than the Royal Muscadine; it is preferable to the Sweetwater, which generally forms a ragged bunch in consequence of a great number of the berries being small and abortive; the Black Prince and Esperione will sometimes succeed; and the Early Black July and Burgundy Black Cluster will ripen still better, but the bunches of the latter are very small.

The only fruits still remaining to be noticed, the varieties of which are of any importance, are figs, gooseberries, and currants, and pineapples.

In some parts of England the *Fig* bears in the open air; but in order to ensure its doing so, a warm, or more strictly speaking, a dry subsoil is absolutely necessary, whether it be grown as a standard in the open ground or against a wall, or forced under glass. Wherever the soil is retentive of water, it will retain the coldness of winter till late in the spring. In fact, if the subsoil be very wet, its temperature will approximate to that of spring water, which in England is little above 50° Fahr. throughout the whole year; an amount of cold which the roots of the fig are certainly not accustomed to in summer in its native climate in Asia and Barbary, or even where it has been naturalised in the South of Europe. Or, if the springs should fall so low during summer, as to leave the roots of the fig tree unaffected by their presence, the temperature of the surface will be suddenly raised by the first rain that falls. This often takes place towards the end of summer, and a superabundant growth ensues, too late for being completed before winter. Figs succeed well in Sussex, where the subsoil is chalk, and the rain passes off as it falls; and in preparing borders for it, the whole should be composed of such materials as are pervious to water. Some of the finest varieties of figs for this climate are the Brown Turkey, Brunswick, White Marseilles, Nerii, Pregussata, White Ischia, Brown Ischia, Yellow Ischia. The Brown Turkey is well adapted for forcing, for which purpose the Pregussata, White Marseilles, and the White, Brown, and Yellow Ischias are also proper.

Gooseberries are brought to greater perfection in Britain than in any other country. The varieties are numerous, and many of them have been raised in Lancashire, chiefly by the manufacturing population, with a view to prizes. It is to be regretted that the latter have generally been awarded solely with reference to weight; hence a number of large but coarse sorts have been brought into cultivation. In making the following selection, flavour and not size has been kept in view.

Fruit, red: Red Champagne; Red Warrington; Keen's Seedling Warrington; Rough Red, used for preserving; Red Turkey; Rob Roy; Ironmonger. *Fruit, yellow:* Yellow Champagne; Early Sulphur; Rumbullion, which is much used for bottling. *Fruit, green:* Early Green Hairy; Pitmaston Green Gage; Green Walnut; Parkinson's Laurel; Massey's Heart of Oak; Edwards's Jolly Tar. *Fruit, white:* White Champagne; Early White; Woodward's Whitesmith; Taylor's Bright Venus; Cook's White Eagle; White Honey.

The varieties of *Currants* preferable for cultivation are very few. Of black currants, the Black Naples and the Black Grape are the best. The White Dutch, Red Dutch, Knight's Sweet Red, and Knight's Large Red, are the best sorts of white and red currants.

The *Pine Apple* is the only tropical fruit which is cultivated to any extent in this country. The best varieties are the Queen, Moscow Queen, Black Jamaica, Brown Sugarloaf, and Black Antigua; the Enville and White Providence are cultivated more for their size than flavour.

FRUITS, PRESERVATION OF. The apple and pear, the two staple fruits of this country, are of so much importance to great numbers of persons, that we shall not dismiss this subject without giving some information concerning the best means of preserving them during the autumn and winter; for it is an object of no little moment to be able to prolong the duration of the season of these fruits even for a single month.

A few early varieties may be eaten from the tree, or when recently gathered; but the greater and by far the most valuable portion require to be kept for some time until they acquire a proper degree of mellowness: thus, most pears are extremely hard when gathered; some even remain so during the winter, and only become melting, or of a buttery consistency, in the spring. Apples, although it is their property to remain a long time nearly as crisp as when gathered, yet are at first too acid for the dessert, and require to be stored up in the same manner as pears, until their juices acquire a rich sugary flavour. Many varieties indeed permanently retain their acidity, but such are only proper for culinary purposes, for which indeed their briskness renders them eligible.

With regard to the gathering and storing of apples or pears, having in view their most perfect preservation, it is necessary that the gathering should be performed in all cases when the trees and fruit are perfectly dry. No precise time can be specified as to the period of the season when any particular variety ought to be taken; for this is influenced variously by circumstances connected with soil, climate, and situation. The best general rule is, to gather when the fruit-stalk separates easily from the spur, on the fruit being raised by the hand from its natural or pendulous position. There are scarcely any exceptions to this rule, unless as regards a few of the summer and early autumn varieties, in which the flavour is improved by gathering a little earlier than is indicated by the above criterion.

The treatment of the fruit after gathering is by no means uniform; some lay it directly on the shelves of the fruit-room, or wherever else it is intended to remain till fit for use; others cause it to undergo a process of fermentation, called sweating, by throwing it in a heap, and covering it with some dry substance, generally straw; in some instances even blankets have been used for this purpose. After it has perspired for ten days or a fortnight, it is spread out at a time when the air is dry, in order to expedite the evaporation of the moisture. All unsound specimens, or even such as are suspected of being so, are then separated. In the case of particularly valuable sorts, it has been recommended to wipe off the moisture with flannel; but this proceeding, for reasons hereafter to be explained, is not advisable.

With regard to the final storing up, as it has been proved by experience that certain methods successfully practised by some, have turned out a failure when attempted by others, and as these fruits are extensively cultivated by persons variously circumstanced, some of whom are compelled by necessity to practise perhaps not the very best mode, but the best they can command, it will be proper to detail the various methods that have hitherto been tried, in order that such as are most deserving of recommendation may be pointed out, as well as those which ought to be avoided in every possible case.

The following are the different modes in which apples and pears have been deposited for winter use:—1. In single layers on the bare shelves of a fruit-room. 2. In the same manner, but covered with light canvas, which must be dried occasionally, as it absorbs the evaporation. 3. In close drawers; one layer, or several layers in depth. 4. In dry casks without any interposing material; a few weeks after they are first put in they require to be carefully picked over, the casks made perfectly dry and re-filled, the head closely fitted, and the fruit on no account disturbed until unpacked for use. 5. In boxes, casks, large garden pots, or jars, with pure and dry sand interposed between the layers of fruit. 6. In jars in which no sand or other substance is allowed to come in contact with the fruit, the mouths of the jars being covered with a piece of slate, and the whole plunged in a quantity of dry sand, so as to be several inches from the free atmosphere. The sand being a slow conductor of caloric, the sudden changes of temperature and their powerful effects in causing the decay of fruits are avoided. 7. In heaps in a dry airy loft, a slight covering of straw being given to protect them from frost. 8. In baskets lined with straw. 9. In close cellars excluded from the light, which is in all cases injurious. 10. In dark but airy vaults. 11. On a small scale, under a bell-glass cemented down air-tight; this must not be done on wood the least resinous, for even the white deal, which, when made into open shelves, communicates none of its flavour to the fruit, yet when supporting a close bell-glass, strongly taints whatever fruit is placed in it, by the confined and accumulating exhalation. 12. Buried in a box placed on four bricks, under another box inverted, in an excavation so deep that the upper portion of the fruit may be 1½ or 2 feet below the surface of the earth. 13. In threshed grain, or in corn stacks. 14. Reposing on wheat straw, with or without a covering of the same. 15. In chaff of wheat or oats. 16. In flax-seed chaff. 17. In powdered charcoal; this, if it cannot prevent, will in no degree contribute to decay, either internally or externally. It is the substance in which the imported Newtown pippins are frequently packed, and they would arrive much sounder than they do were it not for the bruises they evidently appear to have received previous to exportation. 18. In dried fern leaves.

Amongst so great a variety of modes, it is obviously of considerable importance to ascertain not only which are the best, but which experience has proved to be the worst. This inquiry is most advantageously pursued by settling in the first instance what the circumstances are that have been universally found detrimental to the preservation of fruits. As was remarked when mentioning the sixth mode, atmospheric changes have very great, if not the most powerful influences; firstly, as regards their caloric effects, and secondly, their hygrometrical. In the former respect, the expansion and condensation occasioned by the rise and fall of temperature must work a change in the state of the juices, doubtless often at variance with the gradual chemical change which these juices naturally undergo; hence, those fruits that are most exposed to vicissitudes of temperature are found to be most apt to fail in attaining their full sugary mellow perfection. Again, when warm weather suddenly succeeds cold, the air in the room is of a higher temperature than the fruit, until such time as the latter acquire from the former an equality of temperature; and until such time as this takes place, the fruit, from its coldness, acts as a condenser of the vapour existing in the warmer atmosphere by which it is surrounded, and the surface consequently becomes covered with a great deposition of moisture, as will be the case with a glass filled with water colder than the atmosphere of a room into which it is brought. The more smooth and glossy the variety of apple or pear, the greater is the condensation on its surface. Russeted apples and pears exhibit the least effects in this way, their rough dry coat being in less immediate contact with the cold juices of the fruit.

From the above it is sufficiently evident that variations in the state of the atmosphere, as regards its temperature, have injurious effects by the expansion and condensation of the juices, and by the deposition of moisture on the surface, partly owing to atmospheric humidity, but chiefly to the circumstance of the latter being condensed upon the fruit, as above explained. This deposition of moisture tends to decompose the skin, and to render it less efficacious as a protector. It therefore follows, that where fruit is not kept closely packed, it should be exposed to as little change of temperature as possible, and should also be preserved from the full effects of an atmosphere saturated with moisture. If a circulation of air could be secured of a uniform temperature and dryness, or nearly so, there is no doubt as to the superiority of flavour which the fruit would acquire. The watery particles would exhale, and at the same time shrivelling would not take place to any great extent, for this chiefly occurs in consequence of expansion and contraction, and alternate moisture and dryness of the surface, the results of irregularities in the state of the atmosphere. It may be here observed, that wiping the fruit is injurious. The skins of fruits are more or less covered with a secretion, technically called the *bloom*, which every one will have observed on grapes and plums, on both of which it is very conspicuous, and although less so on apples and pears, yet it does exist on them, and its use is to protect, in a great measure, the skin from the effects of moisture. Some fruit-growers are so well aware of this that they will not even handle their most choice wall-pears in gathering, except by the stalk.

Light is found to be injurious; all agree that fruit keeps best in total darkness. This arises from a specific stimulus being exercised upon the vegetable tissue by this agent. If a leaf, a green branch, or such a green surface as that of an apple or pear be exposed to light, even in the most diffused state, evaporation takes place; but as soon as the stimulus of light is withdrawn, evaporation ceases. Speaking of plants in general, evaporation from the green parts takes place all day long and ceases at night.

The preceding observations will explain the reason why a fruit room is best in a dry situation, on the north side of a wall or other building where the sun's heat will not readily disturb the temperature. The roof should be double, and the walls hollow; the windows small. There should be a full command of ventilation; but the room should also be capable of being entirely shut up.

Ventilation should be used only when the air, owing to the exhalations from the fruit, is not perfectly sweet; when this is not the case, air must be admitted in whatever condition it may happen to be; but it would be most desirable to admit air copiously *only when it is of an equal temperature with that of the interior of the room.* The latter should be in two or three compartments, in order to keep the late sorts entirely free from the contaminating effects of exhalations of fruit in a fully ripe state.

These being the conditions under which the ripening, decay, and preservation of apples and pears always take place, the reader will have no difficulty in judging of the relative advantages of the 18 methods already named. It is obvious that Nos. 1, 2, 3, 4, 5, 6, 7, are plans in which the circumstances essential to the preservation of fruit are nearly completely complied with. Nos. 8, 11, 14, 15, and 16, are bad, either because of the liability of the material in which they are packed to decomposition, by which the fruit acquires a tainted musty taste, or because they can only be applied on a very small scale. Nos. 9 and 12 are chiefly objectionable because, owing to the almost total absence of evaporation, the fruit, although well preserved and plump, is apt to be watery and tasteless. No. 17 is a troublesome and dirty practice; Nos. 13 and 18 are excellent when opportunity occurs of practising them; but No. 10, in dark but airy vaults, is undoubtedly that which most completely complies with the conditions necessary for preservation, and is much the best. We have known apples, that are usually decayed in February, preserved till Midsummer in this manner, in all their freshness and colour, and nearly all their flavour.

With regard to nuts and walnuts, the only precaution that it is necessary to take for their preservation is to maintain the air in which they are placed in a constant state of moisture. Burying in the earth, placing in a damp cellar, mixing with damp sand, and many such plans have been recommended; but they are all objectionable, either because they keep the fruit too moist, or do not offer any impediment to its becoming mouldy. We believe the best of all plans is to pack them in glazed earthen jars, throwing a small quantity of salt on the last layer before the jar is closed.

Apples and pears dried in ovens may be preserved for years. Bosc states that he has tried the latter, after three years' preservation, and found them still good; but they are best during the first year. They are placed in the oven after the bread is drawn. The process is repeated a second, third, or fourth time, according as the size or nature of the fruit may require. The heat must not be so great as to scorch, nor must the fruit be dried to hardness. When properly done, they are kept in a dry place. Another method, chiefly practised on the rousselets, and of these the rousselet de Rheims is the best for the purpose, is to gather the fruit a little before maturity; after being half boiled in a small quantity of water, they are peeled and drained. They are then placed in the oven, and heated to a suitable degree, for twelve hours. They are then steeped in syrup, to which have been added brandy, cinnamon, and cloves. They are again returned to the oven, which is heated to a less degree than at first: this operation is thrice repeated.

The flattened dried apples, called *beaufins*, so abundant in the London shops, are, as stated above, prepared in Norfolk, from a variety of apple called the Norfolk beaufin: it has a thick skin, which resists, without bursting, the heavy pressure to which the apples are subjected in the oven, during the slow and lengthened process of drying.

FRUIT-TRADE. This trade, as far as printed returns can show, is necessarily confined to foreign produce. Almost all the fruit grown at home is consumed at home. Our orchards and market fruit-gardens, however large, yield no surplus produce for us to sell to the foreigner; nor, indeed, could we sell it at a price that would yield an adequate profit after defraying the cost of carriage. Nor have we any means of knowing how much fruit is grown and eaten in England; the orchard-keepers and fruit-growers are not required to render to any one an account of the amount of their trade. Occasionally attempts are made to estimate these quantities. Some years ago, Mr. H. Mayhew, in the 'Morning Chronicle,' gave a tabulation which professed to be an account of all the fruit sold at Covent Garden Market in one year. Mr. Braithwaite Poole, goods'-manager on the greatest of our railways, presented an estimate of the quantity of fruit sold in all the markets of the metropolis in 1850, comprising such items as 17,000 tons of apples, 9000 tons of pears, 7000 tons of gooseberries, 4500 tons of plums, 4000 tons of currants, 1000 tons of damsons, 900 tons of cherries, 700 tons of strawberries, 230 tons of filberts, 230 tons of hazel-nuts, 50 tons of mulberries, and so forth. In so far are these estimates are reliable, they give a curious insight into the vast dealings and consumption of the metropolis; but they do not afford safe data for any inferences concerning the United Kingdom at large.

We will select 1856 as a year to illustrate the extent of the foreign fruit-trade; not because it was the latest available, but because it affords a pretty fair average of recent years. The imports of foreign fruits, in kinds and quantities, in the above-mentioned year, were :—

Almonds, sweet	34,000 cwts.
„ bitter	9,000 „
Apples, raw	530,000 bushels
„ dried	2,000 „
Currants, dried	350,000 cwts.
Figs, dried	44,000 „
Grapes	12,000 bushels
Chestnuts	67,000 „
Cocoa nuts	1,880,000 No.
Hazel nuts	218,000 bushels
Walnuts	56,000 „
Oranges and lemons	690,000 „
Pears	22,000 „
Plums	3,500 cwts.

Prunes	17,000 cwts.
Raisins	270,000 ,,
Tamarinds	1,400,000 lbs.
Various	97,000 bushels

Some of these were exported to other countries; the home consumption did not quite reach the above quantities.

FRUSTUM, a portion cut off from any solid figure. The term is most frequently applied in the case of the cone, and conoidal surfaces of revolution. By " frustum of a cone " is meant any part cut off from a cone which does not contain the vertex. This distinction is drawn because any part of a cone which contains the vertex is another cone.

FUCUSAMIDE ($C_{20}H_{12}N_2O_6$). An organic compound much resembling furfuramide, with which it is isomeric; obtained by the action of ammonia upon *fucusol.*

FUCUSINE ($C_{20}H_{12}N_2O_6$). An alkaloid isomeric with furfurine, obtained by boiling *fucusamide* with caustic potash or soda.

FUCUSOL ($C_{10}H_4O_4$). An organic substance isomeric with *furfurol*, obtained by distilling marine algæ with dilute sulphuric acid.

FUEL is any combustible matter employed for the purpose of creating and maintaining heat. In the early ages of the world, wood must have constituted, as indeed in many countries it does to this day, the principal fuel employed. Wood consists chiefly of three elements, —carbon, hydrogen, and oxygen. The two former are both of them highly combustible, hydrogen being especially so, and giving rise to the flame with which wood is well known to burn. When the smoke occasioned by the combustion of wood is found inconvenient, or when the fuel is required to last for a longer period in a given bulk, then charcoal is employed, which is merely wood that has undergone imperfect combustion, so as to expel its hydrogen and oxygen, and to leave the greater part of the carbon.

Another kind of fuel, which doubtless was early in use on account of the facility with which it is obtained from its nearness to the surface, is *peat*, or, as it is sometimes called, *turf*. This is a congeries of vegetable matter, in which the remains of organisation are more or less visible. Peat is the common fuel of a large part of Wales and Scotland, and of many districts of England, where coal is not readily procured.

In this country, however, coal furnishes the great supply of fuel, and its various kinds are employed in different ways and for different purposes, according to its nature and that of the substance to be acted on by its agency. When coal, by a process analogous to that by which charcoal is procured from wood, is freed from its more volatile constituents,—hydrogen, oxygen, and nitrogen,—it is converted into coke. It then burns with but little flame and no smoke, and is used for giving an intense degree of heat in the reduction of most metallic ores, especially those of iron. In some cases a mixture of coke and charcoal is very advantageously employed, especially in assaying in the small way. The mixture gives out a great degree of heat while burning, and being more combustible than coke alone, small furnaces, in which the draught is less powerful than in larger ones, are particularly adapted for its use; and though it consumes faster than coke, it lasts longer, gives a greater heat, and is more economical than charcoal alone.

In some countries, even the dried excrement of animals is used as fuel; and from the use of camels' dung the formation of sal ammoniac was derived in Egypt; this salt subliming from the excrement during its combustion.

In small chemical operations, as for the blow-pipe, tallow or wax candles are frequently employed; and in lamps, oil, spirit of wine, or methylated spirit are employed, and at the present time coal gas is almost universally used, either for the purpose of boiling or evaporating small quantities of fluids, or dissolving various bodies in different menstrua.

During the combustion of different kinds of fuel, the products vary: thus, when wood, coal, wax, tallow, oil, alcohol, or coal gas is employed, the principal products are carbonic acid gas and water; when charcoal is used, carbonic acid is almost the only volatile substance formed, for the hydrogen which the wood contained is expelled by the process of charring.

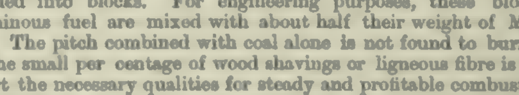
The sources of ordinary fuel will be found sufficiently described under CHARCOAL, COAL, COKE, GAS-LIGHTING, &c. A few words may, however, usefully be said concerning some of the kinds of *artificial* fuel introduced within the last few years. Oram's patent fuel was planned with a view to make use of the small coal which is so extensively left to waste at the mouths of the pits; this coal to be mixed with earthy substances, such as sand, marl, clay, or alluvial deposit; or with some bituminous substance, such as mineral tar, coal tar, gas tar, pitch, resin, or asphaltum; or with saw dust, coke dust, or breese. In short, this was one of those vague patents which defeat their own purpose by the wideness of their grasp. Mr. C. W. Williams, managing director of the Dublin Steam Packet Company, has patented three or four inventions for artificial fuel in which peat shall be one of the ingredients. The peat, after being partially dried, is pressed with great force, to expel the remaining moisture; and it is then mixed with some bituminous substance. By different modes of treatment Mr. Williams produced a very dense brown combustible solid, a charcoal twice as compact as hard wood charcoal, an artificial coal, and an artificial coke. Mr. Bethell's patent fuel consists of small coke and dust from gas works, or breese; the breese is mixed with coal tar and put into a coke oven, where it is burned into good coke. If burned in open heaps, it would also produce coke, but of inferior quality. Seventy-five per cent. of breese is found to be a good proportion with twenty-five of pitch or coal-tar. Instead of coke, bricks of artificial fuel are sometimes produced by casting the mixture into iron moulds, and baking. Mr. Warlich's patent fuel is employed rather extensively; it is made of some such mixture of materials as Bethell's, but with especial attention to its fitness for use in marine engine furnaces, locomotive furnaces, and stationary engine furnaces. In the investigations made by commissioners employed by the Admiralty, into the qualities of various kinds of fuel adapted for the engines of H. M.'s steam navy, Warlich's, and some other kinds of artificial fuel, were found to be favourable, when alternating under certain conditions with good coal. Dr. Arnott, in a Report on the Paris Exhibition of 1855, said :—" A very important object exhibited was a prepared fuel called the *Charbon de Paris.* The manufacturer takes fragments or dust of bituminous coal, or of anthracite, charcoal, or coke, and mixing these in certain proportions with coal-tar, &c. makes a soft mass, which, by moulding, he shapes into cylindrical pieces about four inches long by one and a quarter in diameter; and he afterwards hardens them by heat, these being very like charcoal, free from slate, and giving intense heat. There are now many makers of such fuel, seeming to believe the excellence of their product to depend chiefly on the proportions of the ingredients, and attributing too little to the uniform size and shape of the pieces, which allow that rightly proportioned approach of air to them on which perfect combustion so much depends. There were in the Exhibition many specimens, both continental and English, of artificial coke or fuel of kindred composition, in much larger masses. An obvious advantage of such over common coal is that the lumps, when put together, occupy less space than an equal weight of irregularly-broken common coal, and therefore can be stowed more advantageously in ships. And in the composition, there may be of bitumen or pitchy matter just what aids the steady combustion without causing smoke; having, therefore, neither the excess nor the deficiency found in many natural coals."

Nearly all these kinds of artificial fuel consist of small coal, small coke, ashes, and bituminous substances, combined in various numbers and various degrees, and subjected to different modes of manipulation. There is one exception, however, in the case of the Trinidad pitch fuel, with which no kind of coal or coke is mixed. There is a great pitch-lake on that island; and a company has been formed for converting the pitch into fuel, by mixing it with wood shavings. The pitch, thoroughly wetted, is mixed with about eight per cent of shavings, and is then moulded into blocks. For engineering purposes, these blocks of bituminous fuel are mixed with about half their weight of Merthyr coal. The pitch combined with coal alone is not found to burn well; but the small per centage of wood shavings or ligneous fibre is said to impart the necessary qualities for steady and profitable combustion.

FUGUE, in music, is a composition in which a subject, or brief air, passes successively and alternately from one part to another, according to certain rules of harmony and modulation. Such is Rousseau's definition, which would have been more complete if he had added that the Fugue is also formed after rules peculiar to itself. The term seems to have originated about the middle of the 15th century, and is commonly supposed to be derived from the Latin word *fuga* (flight), because the theme, or point, flies from part to part; but this etymology is by no means satisfactory, though we certainly have no better to offer.

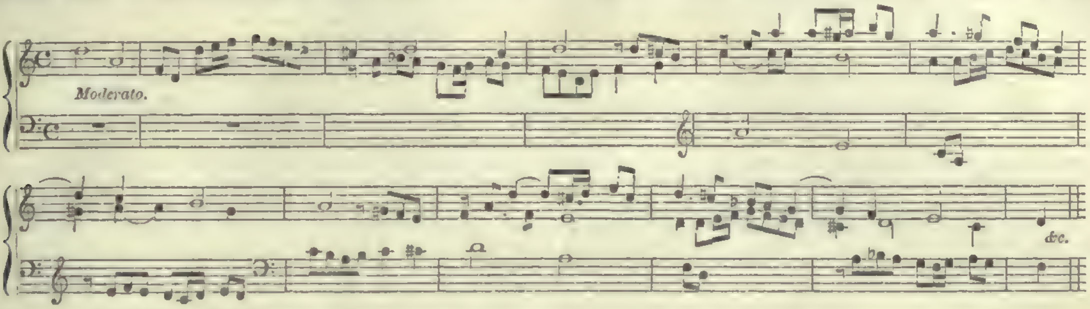
Writers on music enumerate many kinds of Fugue, the chief of which are, the *Strict Fugue*, the *Free Fugue*, the *Double Fugue*, and the *Inverted Fugue*; to which we shall add that species—for it decidedly belongs to the Fugue genus—called *Imitation.*

" In a Strict Fugue," says Dr. Crotch (' Elements of Composition '), " the subject is given out by one of the parts, then the answer is made by another; and afterwards the subject is repeated by a third part, and, if the fugue consist of four parts, the answer is again made by the fourth part: after which the composer may use either the subject or the answer, or small portions of them, in any key that he pleases, or even on different notes of the key." In this severe kind of composition, when the subject, or leader, or point, or *dux*, or by whatever name the theme may be designated, is comprised between the tonic and the dominant the answer (or *Comes*) must be given in the notes contained between the dominant and the octave. Example:



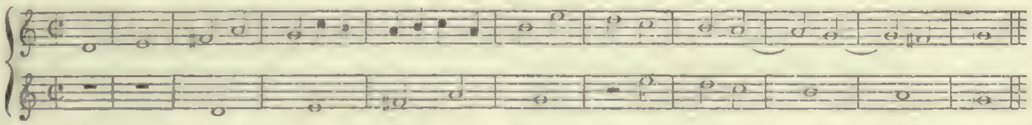
The chorus, ' He trusted in God,' in the ' Messiah,' is a fine specimen of this sort of fugue, to which we refer the reader; for few persons are without that sublime oratorio in some form.

In the Free Fugue much more latitude is allowed the composer; he is not so restrained by the subject, but may introduce what Albrechtsberger terms episodes—passages not closely related to the theme, though they should never be very foreign to it. The overture to the 'Zauberflöte' affords a splendid example of this species. The Double Fugue consists of two or more subjects moving together, and dispersed among the different parts. Dom. Scarlatti's in D minor is a double fugue which has no superior of its kind. The first few bars of this will more clearly explain than words can do the nature of so elaborate a species of composition.



Fugues of more than two subjects are classed, not very correctly, among double fugues; they are, however, rare, for which reason perhaps they have never received a distinguishing name. Of these the fugue of four subjects in the finale to Mozart's grand symphony in C, and that of the same description in Handel's *Alexander's Feast*, the chorus 'Let Old Timotheus yield the prize,' are master-pieces of their kind. All of this species must be considered as free fugues. The term Fugue by Inversion requires little explanation. In this the theme is inverted, as the name implies, but the effect arising out of such contrivance is appreciable only by those who know its difficulty, and estimate its merit by the quantity of labour it has cost. In the Fugue by Augmentation, the notes of the answer are doubled in length. In the Fugue by Diminution, exactly the reverse takes place. There are other kinds of Fugue, but they are now almost forgotten, and it would be useless to revive their names.

Imitation is a species of fugue, and by theorists is generally treated on previously to and as the precursor of the latter. As the word indicates in this kind of composition, the theme is more or less imitated in the different parts. It is not required, says Fux (*Gradus ad Parnassum*), that every note should be imitated, but only some part of the subject; and Imitation is rather to take place in the middle than in the commencement of a composition. It may be made in any of the intervals, and in fact is governed by scarcely any rule. The learned contrapuntist just named gives the following as an example of Imitation in the Unison :—



The effect of technical imitation in music is unquestionably great; it is felt by all who have the slightest skill in the art, therefore employed by all great composers of every school, ancient and modern. Canon, which is sometimes called a perpetual fugue, may perhaps be admitted, though cautiously, as part of a course of professional study, but should rarely, if ever, be allowed to pass the boundaries of the school. [CANON.] Fugue, but not of the pedantic or fantastic kind, should be an object of serious attention with those who are ambitious of becoming great composers, though in its severe form it ought to be almost confined to cathedral music and to the oratorio, and is admissible there only when introduced with great discretion, and guided by the hand of an experienced sensible master. But without that which is here to be understood by the term imitation—or the recurrence, in some shape, of the chief subject—music in parts, of even a very simple kind, loses one of its greatest beauties. Let it be used however with a view solely to effect: if resorted to for the mistaken purpose of displaying what a young or a dull composer may call his learning, imitation will prove to be nothing better than mere plodding, and capable of exciting no emotion except that which is the very reverse of pleasing.

FULCRUM. [LEVER.]

FULGURITE. [LIGHTNING; and FULGURITE in NAT. HIST. DIV.]

FULLING. [WOOLLEN MANUFACTURES.]

FULMINATING MERCURY (HgO_2, $C_4N_2O_2$). The compound of *Fulminic Acid* with mercury. It is prepared by dissolving 1 part of mercury in 12 of nitric acid, sp. gr. 1·36, and then adding 11 parts of alcohol, sp. gr. ·850. If a gentle heat be now applied by means of a water-bath violent reaction ensues, metallic mercury is deposited, and minute crystalline grains of fulminate of mercury separate, these must be washed with cold water and dried at 100° Fahr. They explode violently by percussion or heat, or by contact with sulphuric acid. The preparation even of small quantities of fulminating mercury is attended with considerable danger, and ought not to be attempted by any one unacquainted with chemical manipulation. Mixed with six times its weight of nitre it is used for priming percussion caps.

FULMINATING SILVER ($2AgO$, $C_4N_2O_2$). This salt of fulminic acid is obtained by dissolving 1 grain of silver in 20 grains of nitric acid diluted with 50 grains of alcohol. The remaining processes are similar to those used for the preparation of fulminating mercury, than which it is still more dangerously explosive. [FULMINATING MERCURY.]

FULMINIC ACID ($2HO$, $N_2C_4O_2$). An acid which is isomeric with cyanic acid [CYANIC ACID], that is, composed of the same elements in the same proportions, and they appear to have similar saturating powers. Fulminic acid has not yet been isolated, but it exists in the detonating mercury and silver discovered by Mr. Howard. These fulminates, as shown under the respective metals, are prepared by the simultaneous action of nitric acid and alcohol upon them: in this operation the metals are oxidized, and such portions of the carbon of the alcohol, and nitrogen and oxygen of the decomposed nitric acid combine, as to form the fulminic acid. Fulminic acid may be separated from the oxides of silver and of mercury, and combined with other bases, as with potash, and it still retains its power of forming detonating compounds. [CYANOGEN.]

FULMINURIC ACID (HO, $C_6H_2N_3O_5$), *Isocyanuric Acid.* A recently discovered acid isomeric with cyanuric acid. The salts of this acid are obtained by boiling the different fulminates with a solution of a soluble chloride. They crystallise generally with facility, and explode feebly on the sudden application of heat. [CYANOGEN.]

FUMARIC ACID. *Boletic acid.* This acid was first procured by Braconnot from the *boletus pseudo-igniarius* by the following process: the expressed juice is to be evaporated to the consistence of a syrup, and then treated with alcohol, which leaves a white matter; this is to be washed with alcohol, then dissolved in water, and precipitated with a solution of nitrate of lead; the precipitate diffused through water is to be decomposed by sulphuretted hydrogen gas; by evaporating the remaining solution there are obtained impure crystals of fumaric acid, and a very acid mother-water, composed of fungic and phosphoric acids. The crystals of fumaric acid are redissolved in alcohol, which leaves a calcareous salt, and by evaporating the solution purer crystals of fumaric acid are procured. Fumaric acid may also be obtained by submitting malic acid to heat, and it is also present in Iceland moss, fumitory and other vegetables.

Fumaric acid is colourless, crystallises in four-sided prisms; its taste is acid, like that of bitartrate of potash; it reddens litmus, does not alter by exposure to the air; is gritty, like sand, between the teeth. It is soluble in 180 parts of water at 68°, and in 45 parts of alcohol. By heat the greater part of it is sublimed either in prismatic crystals or in fine powder; but towards the end of the operation some empyreumatic oil is formed, and there is a strong smell of acetic acid. It has the peculiar property of precipitating the peroxide of iron from solutions, but not the protoxide.

This acid forms salts with the alkalies and other bases; they are called fumarates. They are not important compounds, none of them being applied to any use. (Berzelius, 'Traité de Chimie,' tom. 5, p. 102.)

FUMARAMIDE ($C_8H_6N_2O_4$). When the *fumarate* of oxide of ethyl, which is a heavy oily liquid, is acted on by *aqua ammoniæ*, it forms a white insoluble powder, which is *fumaramide*, and possesses all the characters of a compound amide.

FUMARIMIDE ($C_8H_3NO_4$?). A reddish amorphous powder, formed by exposing bimalate of ammonia to a heat of about 400° Fahr. Heated for several hours with hydrochloric acid, it yields aspartic acid.

$$C_8H_3NO_4 + 4HO = \underbrace{C_8H_7NO_8}_{\text{Aspartic acid.}}$$

FUMIGATION is the application of the vapour or fumes from metallic or other preparations to the body, with the intention of healing either generally, or particular parts. The vapours of hot vinegar, burning sulphur, and of aromatic vegetable matters, have been long used to counteract unpleasant or unwholesome smells: this is effected chiefly by the formation of such as are stronger. The most important kind of fumigation is that which consists in the employment of such vapours or gases as do not merely destroy unhealthy odours by exciting such as are more powerful, but which by their chemical action convert dangerous miasmata into innocuous matter.

The fumigation of the first kind, that which is intended to produce a healing effect, is now much less employed than formerly; still, however, the bisulphide of mercury is occasionally used in vapour, as what is termed a mercurial fumigation, in certain forms of syphilis. The use of vinegar, of aromatic pastilles, and even the smoke of burning brown paper, which constitute the second kind of fumigation, does not require any particular notice; their operation can hardly be regarded as any other than that of substituting one smell for another. In the last kind of fumigation three substances have been chiefly employed, and in the gaseous state: first the vapour of burning sulphur, or sulphurous acid gas, hydrochloric acid gas, nitrous acid gas, and chlorine gas; all but the last of these, or at any rate the first and second named, appear to have been first used and recommended by Dr. James Johnstone, of Worcester, about the year 1758; in 1773 Guyton de Morveau also mentioned the application of hydrochloric and nitrous acid gases, and in 1802 their use was still further extended by Dr. J. C. Smith, who received a public remuneration as the discoverer, which he certainly was not.

Chlorine gas, which is undoubtedly preferable to any disinfectant, was first recommended by Dr. Rollo, who published a work on diabetes in 1797; he liberated the gas by the usual method of mixing sulphuric acid, binoxide of manganese, and common salt. When it is desirable to produce a great effect in a short time, this is still unquestionably the best mode of proceeding.

We shall give an abstract of the mode adopted by Mr. Faraday in fumigating the Penitentiary at Milbank in 1825. ('Quarterly Journal,' vol. xviii., p. 92.)

The space requiring fumigation amounted to nearly 2,000,000 cubic feet; and the surface of the walls, floors, ceilings, &c., was about 1,200,000 square feet. This surface was principally stone and brick, most of which had been lime-washed. A quantity of salt reduced to powder was mixed with an equal weight of binoxide of manganese, and upon this mixture were poured two parts of sulphuric acid, previously diluted with one part of water, and cold. The acid and water were mixed in a wooden tub, the water being first put in, and it being more convenient to measure than to weigh the water and acid, ten measures of water and nine of acid were used; half the acid was first used, and when the mixture had cooled the remainder was added.

Into common red earthen pans, each capable of holding about a gallon, were put 3½ lbs. of the mixed salt and manganese, and there was then added such a measure of the diluted acid as weighed 4½ lbs.; the mixture was well stirred and then left to itself, and all apertures were well stopped. The action did not commence immediately, so that there was sufficient time for the operator to go from pan to pan without inconvenience. On entering a gallery 150 feet in length, a few minutes after the mixture had been made, the general diffusion of chlorine was sufficiently evident; in half an hour it was often almost impossible to enter, and frequently on looking along the gallery the yellow tint of the atmosphere could easily be perceived. Up to the fifth day the colour of the chlorine could generally be observed in the building; after the sixth day the pans were removed, though sometimes with difficulty, and the gallery thus fumigated had its windows and doors thrown open. The charge contained in each pan was estimated to yield about 5½ cubic feet of chlorine gas; in fumigating a space of 2,000,000 cubic feet, about 700 lbs. of common salt and the same of binoxide of manganese were employed: and it will appear by a slight calculation, that about 1710 cubic feet of chlorine were employed to disinfect this space. In common cases, Mr. Faraday conceives that about one-half to one-fourth of this quantity of chlorine would be sufficient.

When any cause for fumigation is continually recurring, and in some cases almost imperceptibly so, the chloride of lime or soda, and especially of the former, has been within a few years successfully employed by M. Labarraque; the exact nature of these compounds is still under discussion, but the chloride of lime is a substance well known and extensively employed under the name of bleaching-powder.

We shall relate a few experiments performed by M. Gualtier de Claubry, illustrative of the mode in which these substances produce their effects. A solution of chloride of lime exposed to the air for about two months, ceased to act upon litmus, contained no chlorine, but a precipitate was formed in it which consisted entirely of carbonate of lime, without any admixture of chlorine; it was therefore evident that the carbonic acid of the atmosphere had decomposed the chloride of lime, evolved the chlorine, and precipitated the lime. That this was the case was proved by passing atmospheric air through a solution of potash, before it was made to traverse one of chloride of lime; in this case the potash separated the carbonic acid, so that no chlorine was evolved from the solution of chloride of lime, nor was any precipitate formed in it; in fact no change whatever occurred. That it was the carbonic acid which produced this effect, was further proved by passing a current of this gas into a solution of chloride of lime; by this it lost its bleaching power, the whole of the chlorine was expelled, and all the lime converted into carbonate.

In order to show the manner in which these compounds of chlorine and lime, and of chlorine and soda, act on putrid miasmata floating in the air, some further experiments were made in the following manner: Air was passed through blood which had been left to putrefy for eight days; being then passed through a solution of the chloride of lime, carbonate of lime was deposited, and the air was rendered inodorous and completely purified. In a second similar experiment the fetid air was passed through a saturated solution of potash before it arrived at the solution of chloride of lime; the latter had then no effect upon it, and the air retained its insupportable odour; this happened evidently because the carbonic acid, which would otherwise have evolved chlorine to have acted upon the putrid matter, was absorbed by the potash. Another experiment was made with air left for twenty-four hours over putrescent blood; the portion of it which was passed directly through the chloride was perfectly purified, but when previously freed from carbonic acid the chloride had no effect upon it.

These experiments sufficiently prove that the carbonic acid in the air, arising from the various sources of respiration, combustion, and the decomposition of animal and vegetable matter, liberates the chlorine from its combination with lime or soda; and as this action is slow, the chlorine, though scarcely susceptible of affecting the animal economy, readily decomposes putrid miasmata. It is therefore true fumigation by chlorine, only it is less violent than that effected by the rapid evolution of the gas, and it continues for a longer time.

It is to be observed that chloride of lime is used in solution, and is obtained by dissolving one part of bleaching powder in about 100 times its weight of water, and allowing the solution to become clear. This is to be exposed to infected air, or in rooms which have any unpleasant odour, in flat vessels, in order that a sufficient surface may be acted upon. If it should be required, the operation may be quickened by the addition of a little vinegar, or of muriatic acid largely diluted. In some cases, where the disagreeable smell is extremely strong, and where it would be difficult to expose a solution to slow action, it may be thrown into the place, or the powder may be used, the action of which would be more gradual and effectual. Chloride of soda is prepared only in solution; the process is given in the last edition of the 'London Pharmacopœia:' it is however less easily obtained than the chloride of lime, is more expensive, and not in any respect preferable; the solution is then called liquor sodæ chlorinatæ.

FUNCTION, ARBITRARY. In the integration of partial differential equations, arbitrary functions are introduced, that is, functions which may be of any form whatsoever. Thus, in the problem of the vibrations of a thin column of air, which leads to an equation of the form

$$\frac{d^2z}{dx^2} = a^2\frac{d^2z}{dy^2}$$

the complete solution of the equation is

$$z = \phi\,(y + ax) + \psi\,(y - ax)$$

when ϕ and ψ stand for any functions whatever. The determination of these arbitrary functions must depend upon the data of the problem. Thus, if it were required so to determine ϕ and ψ as that z should become x when y is x, and x^2 when y is bx: we have then to determine the forms of ϕ and ψ from the two equations

$$\phi\,(x + ax) + \psi\,(x - ax) = x$$
$$\phi\,(bx + ax) + \psi\,(bx - ax) = x^2$$

These two functional equations might be solved without much difficulty, and forms of ϕx and ψx found. Theoretically, the determination of the arbitrary functions, so as to satisfy given conditions, resolves itself into the solution of functional equations.

But when these questions were first considered, it was soon seen that the problems from which they are derived present very peculiar circumstances. For instance, when the problem is that of finding the manner in which a disturbance travels along a thin column of air, the preceding equation exists, where z represents the amount of compression or rarefaction which exists in the air at a distance y from a fixed origin at the end of the time x from the beginning of the motion. Now, in practice, there is no disturbance of the state of the air at the beginning of the motion, except in one small part of the column (as in a sound excited at one end of a cylindrical tube). Suppose, for example, that by introduction of external air, a certain amount of compression, c, is generated at the first moment ($x = 0$) throughout the portion of the tube which extends from $y = 0$ to $y = m$. When $x = 0$, z is $\phi y + \psi y$, and the conditions of the problem require that $\phi y + \psi y$ should be equal to c when y lies between 0 and m, and always equal to nothing when y is greater than m. Hence, $\phi y + \psi y$ must be a discontinuous function; so that in this simple problem mathematical methods are insufficient to express a solution, unless discontinuous functions can be admitted among the solutions of partial differential equations.

There was, at one time, a spirited discussion between Euler, D'Alembert, and Lagrange, as to whether discontinuous functions could properly be admitted among the solutions of differential equations. We cannot enter into the details of this discussion, but we shall state the manner in which the question has been settled.

The considerations in Curve give some approach to the notion that curves which are perfectly independent may be combined in one equation; and also that a continuous curve may be drawn, the arc of which runs as near as we please to two distinct branches of two independent curves. The power of expression given by means of definite integrals and periodic series [Integrals, Definite], puts this result in a stronger light. Suppose, for example, that an axis of x being taken, we want to express mathematically the ordinate y, in such manner that it shall be nothing from $x = -\infty$ to $x = 0$; that of a certain straight line from $x = 0$ to $x = a$; that of a certain circle from $x = a$ to $x = b$, and nothing again from $x = b$ to $x = \infty$. In other words, we ask whether a line which is both limited and discontinuous, being a part of a straight line and a part of a circle, can be put upon the same sort of footing as an algebraic curve; so that a definite equation $y = \phi x$ shall always give $y = 0$ when there is no ordinate, and shall give the proper value of y whenever there is an ordinate. The answer to this is, that such an expression for ϕx can be given, when the notation of the integral calculus is assumed. And more than this, a *continuous* curve can be found which fulfils all the conditions above noted, as nearly as we please. That is, m being a small quantity which we may name as small as wel please, it is possible to find a continuous curve, the ordinate of which shall never be so great as m from $x = -\infty$ to $x = 0$, shall never differ by so much as m from the ordinate of the straight line while x passes from 0 to a, nor from that of the circle while x passes from a to b, and finally, shall never be so great as m from $x = b$ to $x = \infty$. Having the power of making m as small as we please, we thus trace the expression, as it were, into its final discontinuous form when $m = 0$.

In this manner, it appears that every discontinuous function may be regarded as the limiting form of a continuous one; and the various modes in which this is established take away all idea of danger from admitting discontinuous functions among the solution of differential equations. This subject is well studied in its application to physics.

FUNCTIONS, CALCULUS OF. By the term *function of a quantity* is meant any algebraical expression, or other quantity expressed algebraically or not, which depends for its value upon the first. Thus the circumference of a circle is a function of the radius; the expression $(a^2-x^2)(b^2+y^2)$ is a function of a, b, x, and y. For the distinctive names of functions, see Transcendental and Algebraical.

All algebra is, in one sense, a calculus of functions; but the name is peculiarly appropriate, and always given, to that branch of investigation in which the *form* of a function is the thing sought, and not its value in any particular case, nor the conditions under which it may have a particular value. [Equations, Functional.] For instance, "What is that function of x which, being multiplied by the same function of y, shall give the same function of $x+y$?"—is a question of the calculus of functions.

Various isolated questions connected with this calculus have been treated, from the time of Newton downwards, particularly by Lagrange, Laplace, Monge, and Euler. But the direct solution of functional equations, or at least the first attempt to form general methods in the case of functions of a single variable, appears to have been made by Mr. Babbage and Sir J. Herschel (1810-1813). To the treatise entitled 'Examples of the Calculus of Differences,' by the latter, the former appended another, containing examples of the solutions of functional equations. This last, and the article 'Calculus of Functions,' in the 'Encyclopædia Metropolitana,' are the only formal treatises on the subject of which we know.

A function of x is denoted by ϕx, ψx, χx, fx, Fx, Φx, &c., &c., the first letter being a symbol of an operation to be performed. Thus, Ffx denotes that when the operation signified by f has been performed upon x, that signified by F is performed upon the result. When the same operation is repeated, the results may be denoted by fx, ffx, $fffx$, &c., which may be abbreviated into fx, f^2x, f^3x, &c. For different points of interest connected with the relations of functional forms, see Periodic; Inverse.

FUNCTIONS, THEORY OF, a name given by Lagrange to a view of the principles of the Differential Calculus, of which we have expressed our opinion in the article Differential Calculus. The works of Lagrange, in which its details are to be found, are 'Théorie des Fonctions Analytiques,' first edition, 1797, second edition, 1813; and 'Leçons sur le Calcul des Fonctions,' of which the first publication is vol. x. of the 'Leçons de l'Ecole Normale' (1801); the first separate edition was published in 1797, and the second was published in 1806.

Taking Lagrange's intention to have been the proof that algebra, as it existed in his time, was sufficient to demonstrate the principles of the Differential Calculus without the introduction of limits, we have only to remark that the end is completely attained. [Differential Calculus.] It is plain to any one acquainted with that calculus, that a demonstration of Taylor's Theorem being once attained, all the rest follows. We now proceed to look at the proof of this theorem given by Lagrange, with reference to absolute correctness or incorrectness.

Lagrange first attempts to prove that every function ϕx has this property, that $\phi(x+h)$ can be expanded in a series of the form

$$\phi(x+h) = \phi x + \mathrm{A}h + \mathrm{B}h^2 + \mathrm{C}h^3 + \ldots\ldots$$

He says, firstly, that no negative powers of h can enter the expansion, for if such were the case $\phi(x+0)$, instead of being ϕx, would be infinite. This is true as to any finite number of negative powers of h, but does not exclude an infinite series of negative powers. For instance,

$$\frac{1}{x+h} = \frac{1}{h} - \frac{x}{h^2} + \frac{x^2}{h^3} - \ldots.$$

when $h=0$, *all* the terms become infinite, but the first side of the equation is not infinite. Secondly, he assumes that there cannot be fractional powers of h, for if such were the case, there must be fractional powers in the original function ϕx, and if ϕx had m different values, and if $\mathrm{K}h^{\frac{p}{n}}$ were one of the terms of the development, the n values of this latter, combined with the m values of ϕx, would give mn different values to $\phi(x+h)$, instead of m. In answer to this it may be asked how is it known, *à priori*, that there must be a series of powers of h, *every* value of which is an expansion of $\phi(x+h)$? May it not possibly be true that there is an expression of the form

$$\phi(x+h) = \phi x + \mathrm{A}h^{\frac{m}{a}} + \mathrm{B}h^{\frac{n}{b}} + \ldots.$$

which is true under certain conditions, determining which of the values of the several terms are to be taken? Thirdly, he assumes that (having thus obtained a series, in which only whole powers of h are found) the supposition $h=0$ must reduce it to its first term; an assumption which can only be admitted of such a series as $\mathrm{M} + \mathrm{A}h + \mathrm{B}h^2 + \ldots.$ when it can be made convergent by giving sufficiently small values to h.

Having once proved or assumed that $\phi(x+h)$ can be expanded in a series of the form $\phi x + \mathrm{A}h + \mathrm{B}h^2 + \ldots$ the proof of Taylor's Theorem, given by Lagrange, does not differ from the common one. He calls A the derived function of ϕx, and denotes it by $\phi' x$: generally, if changing x into $x+h$ change P into $\mathrm{P} + \mathrm{P}'h + \ldots.$, P′ is the derived function of P. The derived function of $\phi' x$, denoted by $\phi'' x$, is called the second derived function of ϕx, and so on. By changing x into $x+k$, $\phi(x+h)$, or $\phi x + \mathrm{A}h + \mathrm{B}h^2 + \ldots$, becomes

$$(\phi x + \phi' x \,.\, k + \ldots) + (\mathrm{A} + \mathrm{A}'k + \ldots)h + (\mathrm{B} + \mathrm{B}'k + \ldots)h^2 + \ldots.$$

and by changing h into $h+k$, $\phi(x+h)$ becomes

$$\phi x + \mathrm{A}(h+k) + \mathrm{B}(h+k)^2 + \ldots.$$

These must be the same, since both represent $\phi(x+h+k)$: and by equating the terms which contain the first powers of k, we find

$$\phi' x + \mathrm{A}'h + \mathrm{B}'h^2 + \ldots = \mathrm{A} + 2\mathrm{B}h + \ldots.$$

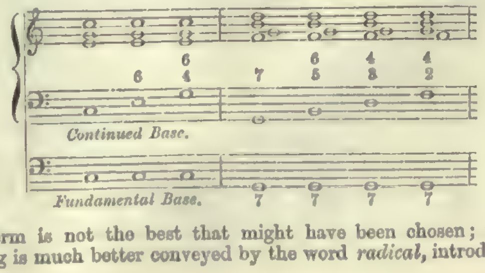
whence $\mathrm{A} = \phi' x$, $2\mathrm{B} = \mathrm{A}' = \phi'' x$, and so on. The reader will recognise in this process the proof frequently given by means of the preliminary lemma, that if

$$u = \phi(x+h), \quad \text{then } \frac{du}{dx} = \frac{du}{dh}.$$

The works of Lagrange on this subject, though defective in their fundamental positions, except upon the explanation given in Differential Calculus, yet abound in new and useful details, given with all the elegance for which his writings are distinguished: and the student will find them well worth his attention.

FUNDAMENTAL BASE, in music, is the lowest note of the Perfect Chord, or Triad, as the Germans call it, and of the chord of the 7th: hence it is the root of all real chords;—for chords not derived from either the perfect chord or that of the 7th, are considered as suspensions or retardations; or, to speak in unaffected language, the discordant notes of which they are composed are simply *appogiaturas*. [Chord.]

The following will show the two *Fundamental Chords*, and their inversions, with the continued [Continued Base], or ordinary base, and the *Fundamental Base*.



This term is not the best that might have been chosen; the same meaning is much better conveyed by the word *radical*, introduced, we believe, by Dr. Callcott. The *system* of the Fundamental Base, founded on harmonics, and a continual addition of thirds to the triad, is indebted for its origin to Rameau, the celebrated French composer [RAMEAU, in BIOG. DIV.], and was once almost universally received. D'Alembert wrote a book to explain and eulogise it, and Marpurg, a most distinguished theorist, adopted it in his 'Handbuch bey dem Generalbasse.' But though it may be rendered in some degree serviceable in the analysis of chords, it is in more than one respect erroneous, and the rules drawn from it by its author would cruelly fetter genius, were they allowed to exert any influence on the composition of music. Rameau's once vaunted system is now therefore entirely laid aside, even in the country that gave it birth.

FUNDS; FUNDING SYSTEM. [NATIONAL DEBT.]

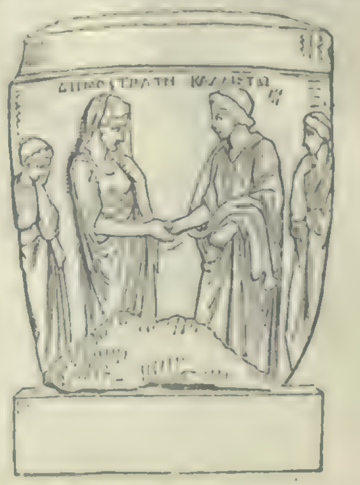
FUNERAL, the performance of the rites of sepulture or burial; generally supposed to be derived from the Latin *funis*, "a torch," because, at least in the Roman times, funerals were sometimes performed by torch-light. Others derive the word from *phónos* (φόνος), "slaughter," as designating death.

The Egyptians are among the earliest people of whose religious ceremonies we have authentic accounts, more particularly in what related to their dead. Upon this occasion the parents and friends of the deceased put on mourning habits, and abstained from gaiety and entertainments. The mourning lasted from forty to seventy days, during which time the body was embalmed, and, when the process was completed, placed in a sort of chest, which was afterwards preserved either in their houses or in the sepulchres of their ancestors. Before the dead were allowed to be deposited in a tomb, they underwent a solemn judgment, upon an unfavourable issue of which they were deprived of the rite of burial. The funeral was conducted with great ceremony. The embalmed body was conveyed on a kind of sledge drawn by cows or oxen, or placed in a boat and towed along the river. In front of the bier, a seated figure representing Anubis is often seen in Egyptian paintings. The sledge was preceded by hired female mourners, with their breasts uncovered, and their hair hanging loose down their backs. The relatives followed, and priests were in attendance to perform the necessary religious ceremonies; but, judging from the ancient paintings of funerals, the arrangements varied considerably with persons of different ranks and at different times. (See Rossellini, plates No. cxxvii., &c.; and Wilkinson.)

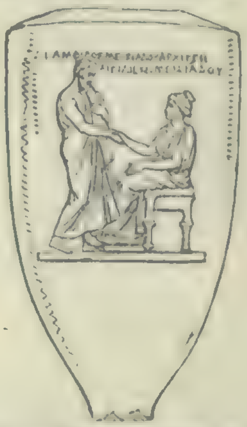
Among the ancient Jews it is clear that great regard was paid to a due performance of the rites of sepulture. (Gen. xxiii. 2-4; l. 7-13; 2 Chron. xxxii. 33; Amos v. 16; and the references to interment generally throughout the Scriptures.) In Egypt and Babylon the Jews seem to have placed the body in a coffin; but elsewhere, both in the earlier ages and in the time of our Saviour, it was customary to wrap the corpse in linen cloths and carry it quickly to the tomb. That they sometimes burnt the body is clear; but burial in a sepulchre was the more usual fashion. (See further, Jahn, 'Jewish Antiquities,' §§ 205–211, and the various commentators on the Bible. The circumstances attending the burial of the dead among the modern Jews are minutely detailed by D. Levi, in his 'Succinct Account' of their Rites and Ceremonies, pp. 162-170.)

In the religious creed both of the Greeks and Romans, sepulture was peculiarly an act of piety towards the dead, without which it was supposed the departed spirit could not reach a place of rest. To be deprived of the proper rites was considered the greatest misfortune (Homer, 'Od.,' v. 311, and xi. 66); and the abhorrence of certain crimes was strongly marked by the refusal of burial to criminals convicted of them. The funeral rites of the Greeks and Romans were in many respects similar, and among both nations the practice prevailed of burning the dead and collecting the ashes in urns. In the case of public funerals, according to Servius's 'Commentary on Virgil,' the deceased was kept seven or eight days, and every day washed with hot water, or sometimes with oil, that in case he were only in a slumber he might be waked; and at stated intervals, his friends, meeting, made a shout with the same view: this was called *conclamatio*. On the seventh day, if no signs of life appeared, he was dressed and placed on a couch in the vestibule, with the feet outwards, as if about to take his departure,—a piece of coin being placed in his mouth for the purpose of paying the fee of the ferryman in Hades. In the course of these seven days, an altar was raised near the bed-side, called *acerra*, on which the friends offered incense. The scene here described is frequently represented in ancient bas-reliefs: several such are in the British Museum. On the seventh day the last "conclamatio" ended, when the couch and body were carried to the *rostra*, where the nearest of kin pronounced the funeral oration, and afterwards to the funeral pile. In the case of persons of importance, the funeral procession was often very splendid. The cost of funerals of persons dying intestate was determined by an officer appointed for the purpose. The body having been consumed, the ashes were gathered, inclosed in an urn, and finally laid in the sepulchre or tomb. An apotheosis, or canonisation, was frequently part of the funeral ceremony of the emperor. A banquet was a part of the funeral ceremony among both the Greeks and Romans. Although the practice of cremation was general with both people, interment was always more or less resorted to. The practice of burning the dead eventually gave way before the spread of Christianity.

In the British Museum are numerous marble cinerary urns (or those which contained the ashes of the dead), both of Greek and Roman date, and others of painted earthenware, both Greek and Etruscan. There are also in the British Museum many solid funeral urns, which were merely commemorative of the deceased; as well as inscribed monumental tablets, and columns, or cippi. We give cuts of two of these Greek urns. The first, a fragment of a fine cinerary urn, is in the Elgin Saloon (No. 275). The young man and woman who are joining hands have their names inscribed above,—Demostrate and Kallisto. The second cut is from a solid funeral urn, 2 feet 3½ inches high, found in the ruins of the Corinthian portico in the bazaar at Athens. It is now in the Elgin Saloon (No. 192). From the inscription we learn that the standing figure in the centre of the bas-relief represents Pamphilus, son of Mixiades, of the deme Ægilia, the seated figure being his sister Archippe.



Cinerary Urn in the British Museum.



Solid Funeral Urn in the British Museum.

The funeral rites of the Greeks and Romans have been collected with great research by Guichard in his 'Funérailles, et diverses Manières d'ensevelir des Romains, Grecs, et autres Nations,' 4to, Lyon, 1581; by Meursius, in his treatise 'De Funere Græcorum et Romanorum,' 12mo, Hag. Com., 1604; by Gutherius, 'De Jure Manium, seu de Ritu, More, et Legibus prisci Funeris,' 12mo, Par., 1613, reprinted in 4to, 1615, and again in 8vo, Lips., 1671; and by Kirchman, 'De Funeribus Romanorum Libri IV.,' 12mo, Hamb., 1605, and Lugd. Bat., 1672. See also the 'Ceremonies Funèbres de toutes Nations,' par le Sr. Maret, 12mo, Par., 1677; Stackeberg, 'Die Gräber der Hellenen,' and Kirchman, 'De Funeribus Romanis.'

For the funeral rites of the early Christians, the reader may consult Gretser 'De Funere Christiano,' 4to, Ingolst., 1611; and he may learn the customs of a later period from Durand, who wrote his 'Rationale Divinorum Officiorum' in the 12th century.

Investigations among the sepulchral tumuli of the northern nations show clearly that though before the introduction of Christianity the practice of cremation prevailed, that of burying the dead unburnt was observed also in the later periods of the pre-historic era, in Norway and Denmark, as well as throughout Germany, France, and England. (See Worsaae's 'Primeval Antiquities of Denmark,' translated by W. J. Thoms, 1849; and the articles CROMLECH and TUMULUS.)

Tacitus, in his treatise 'De Moribus Germanorum,' (c. 27) notices the simplicity of the funerals among the ancient Germans. Like the Romans, they burned their dead. The things which a German valued most were his arms and his horse: these were added to the funeral pile, with a persuasion that the deceased would have the same pursuits in his new state of existence. In the tomb of Childeric, king of the Franks, his spear, his sword, with his other warlike weapons, and even his horse's head, were found. (See Montfaucon, 'Monumens de la Monarchie Françoise,' tom. i. p. 10.)

Brand, in his 'Popular Antiquities,' vol. ii., p. 139 to 212, has much upon the English ceremonials, beginning with 'Watching with the Dead,' called in the North of England the Lake-Wake; he then proceeds with 'Laying out or streaking the Body;' setting salt or candles upon it; funeral entertainments; sin-eaters; mortuaries; following the corpse to the grave, and carrying evergreens, torches, and lights, at funerals; black used in mourning; the pall and under-bearers; doles and donations to the poor at funerals; church-yards; garlands in churches; and strewing flowers upon graves. Strutt's 'Manners and Customs,' Gough's 'Sepulchral Monuments of Great Britain,' and 'Notes and Queries,' vols. vi. to xii. of series 1, are other works to which the reader may refer for the older funeral rites of England.

Funeral entertainments, called silicernia and *cœnæ ferales* by the Romans, are of very ancient date. They are still kept up in the north of England, and are there called arvals or arvils. Among some extracts from the Berkeley Manuscripts, we read that "From the death of Maurice, the fourth Lord Berkeley, which happened June 8th, 1368, until his interment, the reeve of his manor of Hinton spent three quarters and seven bushels of beans in fatting one hundred geese towards his funeral, and divers other reeves of manors the like, in geese, ducks, and other poultry." Walsingham, speaking of those who attended Richard II.'s funeral at Langley, in 1399, says, "Nec erat qui eos invitaret ad prandium post laborem." ('Hist.' p. 405.) Shakspere has a well-known allusion to these feasts in 'Hamlet,' act i. sc. 2:

> "The funeral baked meats
> Did coldly furnish forth the marriage tables."

Lafitau, Charlevoix, and other travellers describe funeral ceremonies not unlike some of those above noticed as prevalent among the savages of America. Robertson ('Hist. of Amer.' vol. ii., b. 4) says, as they imagine that departed spirits begin their career anew in the world whither they are gone, they bury together with the bodies of the dead, their bow, their arrows, and other weapons used in hunting or war; they deposit in their tomb the skins or stuffs of which they make garments, Indian corn, venison, domestic utensils, and whatever is reckoned among the necessaries in their simple mode of life.

FUNERAL ORATIONS, discourses at funerals, are of great antiquity. The second book of Thucydides (c. 35, &c.) contains the laboured harangue delivered by Pericles at the solemn funeral ceremony instituted in honour of those Athenians who fell at the beginning of the Peloponnesian war; and other similar orations are extant in Greek. Augustus, at the early age of twelve, performed this office for his grandmother, and afterwards, when emperor, for the young Marcellus. Tacitus tells us that Nero pronounced a funeral oration over his wife Poppæa. Funeral orations were equally common over Christian martyrs; and Durand, in his 'Rationale,' says, "Ceterum priusquam corpus humo injecta contegatur, defunctus oratione funebri laudabatur." Fuller, in his 'Appeal of Injured Innocence' (part iii. p. 75), and Misson, in his 'Travels in England,' show the continuance of this practice to the close of the 17th century. Gay alludes to it in his 'Dirge:'

> "Twenty good shillings in a rag I laid,
> Be *ten* the parson's for his sermon paid."

The practice of delivering what may be properly called funeral orations, that is, addresses over the grave or at the interment of the dead by laymen, is common among the French, and is not unfrequent on great occasions among the people of the United States. In France the 'Oraisons Funèbres' of Bossuet and Fléchier have deservedly a high reputation.

FUNERAL SHOWS and GAMES frequently followed public funerals among the Greeks and Romans. An early example of this occurs in the funeral games celebrated by Achilles in honour of Patroclus. (Homer, 'Iliad.') As the dead were supposed to be delighted with blood, various animals, especially such as the deceased had been fond of, were slaughtered at the pile, and thrown into it: and, in still ruder times, captives or slaves. Among the Romans, gladiators, called *bustuarii*, were made to fight. Junius Brutus exhibited gladiators at his father's funeral; and the 'Adelphi' of Terence, at a later period, was produced for the first time at the funeral of Lucius Æmilius Paulus.

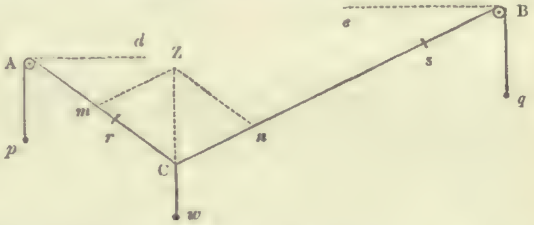
FUNGIC ACID, an acid discovered by Braconnot in the juice of most fungi. This acid exists partly in a free state in the *periza nigra*, and combined with potash in the *boletus juglandis*; it may be obtained from the juice of either of these vegetables by evaporating it to the consistence of a syrup, and treating it with alcohol. The portion insoluble in alcohol is the fungate of potash, which is to be decomposed by acetate of lead; the fungate of lead is to be decomposed by dilute sulphuric acid, or by hydro-sulphuric acid, by which the lead is separated in the state of sulphate or sulphuret, and the fungic acid is left in solution.

This acid, when pure, is colourless, very sour, uncrystallisable, and deliquescent; with lime it forms a salt difficult of solution, and with potash and soda deliquescent uncrystallisable salts; in these and some other properties it resembles impure malic acid. Some doubt exists as to whether it is a distinct acid, and M. Depaignes states that it is merely a mixture of malic, citric, and phosphoric acids.

FUNGIN, the name given by Braconnot to the fleshy substance of mushrooms, purified by digestion in a hot weak solution of alkali: it is whitish, soft, insipid, and but little elastic. It is not acted upon by water, alcohol, ether, dilute sulphuric acid, potash, or soda; it is dissolved by hydrochloric acid when heated, and it decomposes and is decomposed by nitric acid; the results are much gas, oxalic acid, a bitter yellow matter, and two fatty substances, one of which resembles wax, and the other suet; the latter is most abundant. It is a highly nutritious substance, and in many of its properties it strongly resembles cellulose. [CELLULOSE.]

FUNICULAR CURVE. [CATENARY.]

FUNICULAR MACHINE is a name given by some mechanicians to a cord or chain attached at one extremity to an immoveable point, the other end passing over a fixed pulley or friction wheel and having a weight suspended from it; a weight being also suspended from the cord or chain in some part of its length between the fixed extremity and the pulley. The cord or chain becomes thus a mechanical agent, since unequal weights, applied as has been said, may be in equilibrio.



Let A C B in a vertical plane be the position of a cord suspended between two points A and B, but capable of moving freely on a pulley at each of those points, and let w be a given weight suspended from any point C; the weights p and q, which should be applied to the cord, at the extremities vertically below A and B, in order to produce equilibrium, may be thus determined. Through C draw the vertical line C Z to represent the weight w, and draw Z m, Z n parallel to B C, A C, respectively: then, by mechanics, the lines C m, C n will respectively represent the strains in the directions A C, B C, and consequently the weights p and q, which, in the case of equilibrium, must be equivalent to those strains. Now since the angles A C Z, B C Z are known, representing them by a and b, the sine of the angle C m Z may be expressed by sin. $(a+b)$; and by trigonometry,

$$p = w\,\frac{\sin.\ b}{\sin.\ a+b},\quad q = w\,\frac{\sin.\ a}{\sin.\ a+b}:$$

therefore if the cord were attached to a fixed object at one end, as A or B, while capable of moving on a pulley at the other, and a weigh w were applied at any point C in its length, a weight q or p, found as above, would hold w in equilibrio.

Again, let the weights p, q, w, and the position of the pullies at A and B be given, the cord moving freely on the pullies and the weight w being capable of sliding by means of a ring along the cord; then the position of the parts A C, B C of the cord, when the system is in equilibrio, may be found in the following manner. Imagine $m\,n$ to be the parallelogram of forces; then since C Z, C m, Z m may be represented respectively by the known quantities w, p, q, the values of the angles A C Z and C Z m or B C Z may be found by trigonometry. With these, by a geometrical construction, or otherwise, the required positions may be readily determined, since A C and B C make with horizontal lines, as A d, B e passing through A and B angles equal to the complements of A C Z, B C Z.

A cord suspended in a vertical plane between two fixed points and acted on by weights placed at different points in its length, is called a *funicular polygon;* and the form of the suspended cord being given, with the weight to be applied at one angular point as C, the weights at all the other angular points, in the case of equilibrium, may be found thus. Let A and B be angular points on the left and right of C, and having determined the strains represented by C m, C n by the parallelogram of forces at C, construct a parallelogram at A and another at B, having vertical lines passing through A and B for the directions of their diagonals, and having two sides of each coincident in direction with the adjacent sides of the funicular polygon, also making the sides (A r and B s) on A C and B C equal to C m and C n respectively: then the diagonals will represent the weights to be suspended at A and C, in order to counteract the strains in A C and B C arising from the weight w at C. By forming parallelograms in a similar manner at the other angular points, the whole system may be in equilibrio. See 'Hutton's Tracts' (Tract 1, sect. 2, prop. i.).

In like manner may the equilibrium of the rafters in a curb-roof be determined. [Roof.]

FUNNEL, a hollow conical vessel with a small tube issuing from its apex; it is an instrument much used in common and domestic life for conveying fluids into vessels of small apertures, and in chemical operations it is used not only for this purpose but for the important one of filtering. [Filtration.] For the mere purpose of the transfer from one vessel to another of such fluids as do not act upon metals, funnels are commonly made of copper, pewter, or tin plate, and this is especially the case when they are employed for conveying powders into bottles. When, however, they are employed by the chemist with acid, alkaline, or such other solutions as dissolve or corrode the metals, then funnels are made of earthen or stone ware, or of glass. When used for filtration, especially in smaller and nicer operations, those of glass are always to be preferred.

FURFURAMIDE ($C_{30}H_{12}N_2O_6$). A product of the action of ammonia upon *furfurol*. It is isomeric with *furfurine*.

FURFURINE, a substance artificially formed by Mr. Fownes, possessing the properties of a vegetable alkaloid, and forming salts with acids. It is procured by boiling *furfuramide* with solution of caustic potash. Its formula is $C_{30}H_{12}N_2O_6$.

FURFUROL ($C_{10}H_4O_4$). When sugar or starch is acted upon with a mixture of dilute sulphuric acid and peroxide of manganese, there is produced in addition to formic acid, a peculiar oily matter which has been named furfurol. It is produced by the following reaction:—

$$\underbrace{C_{12}H_{10}O_{10}}_{\text{Starch.}} + O_4 = 2CO_2 + \underbrace{C_{10}H_4O_4}_{\text{Furfurol.}} + 6HO$$

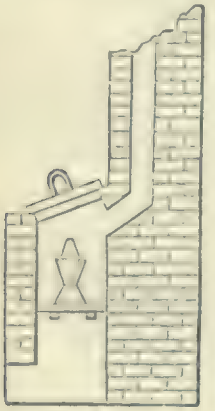
The same body can also be obtained by other reactions. Furfurol is an oily fluid, almost colourless at first, but on exposure to air, it gradually becomes brown, and finally black. It boils at 330° Fahr., and is easily soluble in water and in alcohol. Left in contact with ammonia for several hours, it is completely converted into a yellow semi-crystalline mass of furfuramide.

FURIES. [Eumenides.]

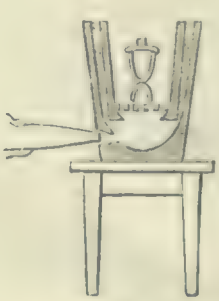
FURLONG. [Weights and Measures.]

FURNACE. The common grate is the most familiar example of a furnace. It is constructed of iron, and of various forms. The fuel is kept in it only by bars, in order to throw the heat out into the room. Indeed this is its principal use; and although its heat is barely sufficient to melt thin plate silver, yet many chemical operations may be performed in the common stove, and its flat sides or cheeks furnish a lower degree of heat, by which evaporation and digestion may be effected. The term furnace is, however, usually applied only to the fire-places used in manufacturing operations, such as those of chemists, metallurgy, and civil engineering.

For the smaller operations in chemistry a great variety of furnaces have been invented. The annexed figure represents one of these, a *wind furnace*: in this a very high temperature is produced without the use of bellows, by means of a powerful draught. The chimney of a wind furnace should be narrow and high; the furnace, represented as connected with and projecting from the chimney, should be of such a height as to allow the operator to look into it; it should be from 12 to 15 inches square, and furnished with moveable bars and a cover; every part exposed to the fire should be constructed of the best fire-resisting bricks. In the figure a crucible is represented as placed in the furnace, and its cover is on. This furnace is much employed in the reduction of metals, and in the assaying of copper and various other ores. The fuel used is either coke, a mixture of coke and charcoal, or anthracite. Another kind is the chemical *blast-furnace*. The exterior consists of a blue pot eighteen inches in height and thirteen inches in external diameter at the top. A small blue pot, of seven and a half inches internal diameter at the top, has the lower part cut off, so as to leave an aperture of five inches. This, when put into the larger pot, rests upon its lower external edge, the tops of the two being level. The interval between them, which gradually increases from the lower to the upper part, is filled with pulverised glass-blowers' pots, to which water enough has been added to moisten the powder, which is pressed down by sticks, so as to make the whole a compact mass. A round grate is then dropped into the furnace, of such a size that it rests an inch above the lower edge of the inner pot: the space beneath it therefore constitutes the air chamber, and the part above it the body of the furnace. A horizontal hole, conical in form, and 1½ inch in diameter on the exterior, is cut through the outer pot, forming an opening into the air-chamber at the lower part, its use being to receive the nozzle of the bellows. The fuel employed is coke, and the furnace is used with a pair of double bellows mounted on an iron frame: the furnace being raised upon an iron stool so as to bring the aperture of the air-chamber to a level with the nozzle of the bellows. Such a furnace as this is sufficiently powerful to melt pure iron in a crucible in 12 or 15 minutes. It will effect the fusion of rhodium, and even pieces of pure platinum have sunk together into one button in a crucible heated by it; all kinds of crucibles, including the Cornish and the Hessian, soften, fuse, and become frothy in it. Mr. Faraday had such a furnace as this long in use at the Royal Institution.

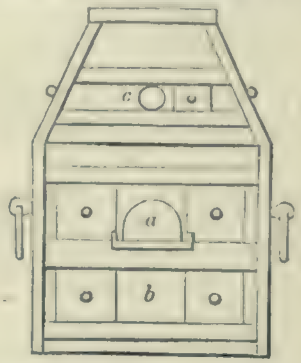


Wind Furnace.

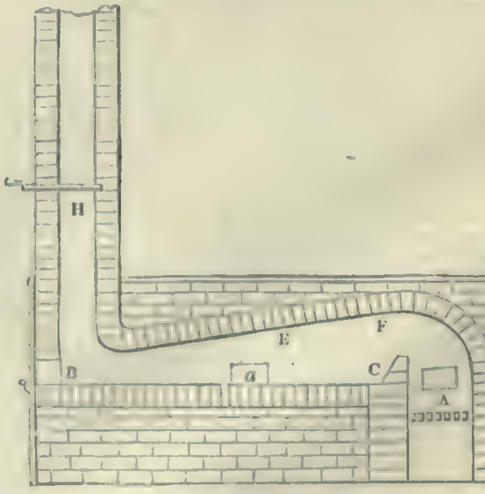


Blast Furnace.

The *assay* or *cupelling furnace* is a small furnace made of iron, lined with fire-proof clay, and containing a muffle; it is used principally for the cupellation of gold and silver, which is placed upon a cupel in the muffle, previously heated to redness. The interior of the furnace contains merely the muffle resting upon two bars of iron; it is put about two-thirds into the furnace, and there is consequently left a space between it and the back part of the furnace. In the annexed cut, *a* is the orifice of the muffle, which may be closed by iron slides placed at the side. The opening *b*, placed below the grate, and provided with slides, serves as well as the upper opening *c* to regulate the draught. Charcoal is used in this furnace.

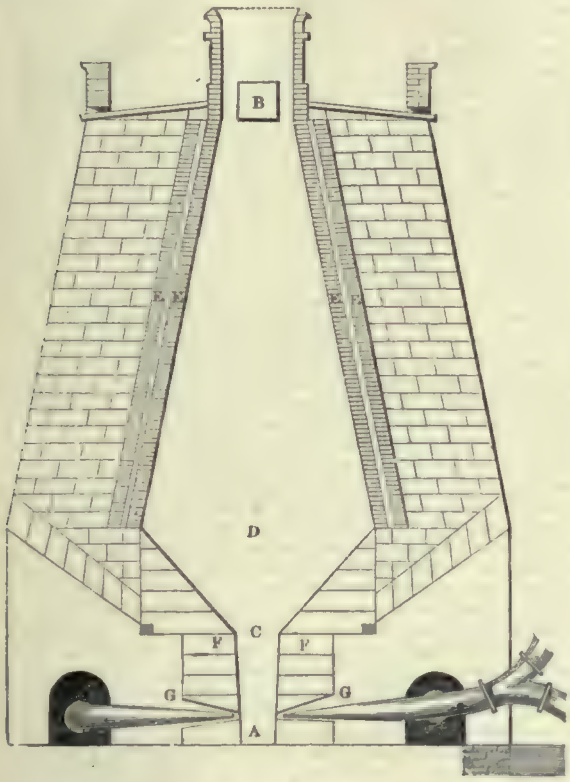


Recently gas furnaces for the analysis of organic substances, and for the fusion of metals, have been ingeniously contrived: the first by Dr. Hofmann, and the latter by Mr. Griffin. The first will be found described in the 'Quarterly Journal of the Chemical Society,' vol. xi., p. 30, and the second in the 'Chemical News,' No. 3. For metallurgic operations on the large scale, as well as in making alkalies, red lead, &c., the *reverberatory furnace* is much used. This is shown in the annexed figure. A is the space furnished with a grate or bars, to contain the combustible, which is either coke, coal, or wood, according to circumstances; B E F is the part on which the flame acts, E F is the roof, B C



Reverberatory Furnace.

the hearth on which the substance to be heated is placed, and this is either horizontal or inclined; lastly, C is a low wall or the bridge of the furnace, which retains the fuel in its place, and serves to direct the flame towards the roof: *a* shows the opening of the furnace, usually placed at its side; through this the substance to be heated is introduced, and it is afterwards closed; often also there is an opening at B, to allow of melted metal to flow out. H is a very high chimney that produces the draught, and which may be closed by a damper. As this furnace is employed for a vast number of purposes, it is evident that various forms must be used; these however it will not be necessary to describe.



Pig-iron Furnace.

The *pig-iron furnace* (see preceding figure) is that used in South Wales and elsewhere in the making of pig-iron; the height of this furnace, from the bottom at A to the filling-place at B, is 50 feet; the height of the hearth, from A to C, 8½ feet; from C to the top of the boshes at D, 8½ feet. The diameter of the hearth from A to C increases from 3 feet to 3½ feet. The extreme width at the top of the boshes D is 11 feet. The diameter of the charging-place B is 6 feet. E E E E, the lining, is composed of a double circle of fire-bricks, about 15 inches long each, with a space for an intermediate packing of sand. F F, the hearth, is constructed of large blocks of breccia, or plum-pudding stone; G G are the tuyers or openings by which the blast is discharged into the furnace from the blowing cylinder, which is worked by a steam-engine. The contents of this furnace are 5015 feet; and it is capable of producing 100 tons of pig-iron weekly.

This important subject of blast-furnaces will receive further elucidation in IRON MANUFACTURE.

In connection with furnaces generally, the new inventions are so numerous as to be quite beyond even enumeration in an article such as the present. Some of the improvements relate to the furnaces of locomotives; some to those of marine engines; some to those of stationary engines; and some to furnaces in general. In one class of cases the patentees seek to economise space, in another fuel, and in another to effect the consumption or prevention of smoke. Some relate to metallic furnaces, and some to brick-furnaces. In some the object is to raise steam in great quantity; while in others it is to obtain rapidity rather than quantity. Many of these new forms of furnace will receive brief notice in the articles relating to Metallurgic, Manufacturing, and Civil Engineering subjects.

FURNISHED LODGINGS. [LODGINGS.]

FURRIERY; FUR DRESSING. The various kinds of fur imported from foreign parts, as well as some found in our own country, may be classed according to their use as *felted furs* and *dressed furs*.

Felted furs. These include all such as are employed in hat-making; and are principally the skins of the hare, the rabbit, the beaver, and the neutria. If the skin be taken off the animal in winter when the fur is full, soft, and fine, it is called "seasoned," and sells at the highest price; but if taken off at any other period of the year, it is comparatively short, coarse, hairy, and less valuable, and obtains the name of "unseasoned skin."

In the preparation of *hares' fur* for the hatter, the skin, after being opened and spread out flat, is rubbed with a kind of saw called a *rake*, for the purpose of clearing away the dirt and dried blood without detaching any of the fur itself. This done, the skin is damped on the *pelt* or inner side; and several are pressed one on another to remove creases and irregularities. Next ensues the separation of the furry covering from the felt beneath. This covering is of two kinds: an external coat of long hairs which possess no felting properties, and an internal coat of fine or true fur. These are removed separately. A pair of shears, something like those used in shearing sheep, are worked all over the surface of the skin so as to cut off the coarse hair without damaging the fine fur beneath; and to effect this properly is a difficult operation. The skin before this shearing was of a brownish colour, but when the external hair is removed the fur beneath appears as a beautiful jet-black glossy fibre. To remove this fur is the next stage. The skin, extended smooth and even, is placed upon a square cutting-board, made of willow, wetted occasionally to avoid blunting the edge of the knife employed in the cutting. This knife is about six inches long by three broad, and has a rough edge; it is shaped something like a cheese-cutter, so as to be used alike backwards and forwards. With such a knife the fur is cut gradually in every part of the pelt; the knife follows the direction which the fur naturally takes on the animal's skin: that is, from the head towards the tail. The whole of the fur from one skin is either collected together as a light fleecy mass, or is separated into parcels according to the different qualities of the different parts.

The preparation of *rabbits' fur* for the hatter is somewhat different from the above in its earlier stages, on account of the greater greasiness of the pelt or inner surface of the skin. By the use of a knife in a peculiar way, the thin cuticle on which the grease or fat is deposited is stripped off, bringing the impurities away with it. The surface beneath is then rubbed with whiting. The rabbit skin, like that of the hare, has two kinds of hair or fur; but the coarser, instead of being removed by shearing, requires to be *pulled;* this is done by a short knife about three inches long, held against a leathern shield worn over the thumb: the hairs are grasped, a few at a time, between the knife and the thumb, and pulled out. A double care is here requisite: to avoid cutting the hair instead of pulling it, and to avoid pulling or cutting the fine fur beneath. When this is done, the fine fur is cut off in the same manner as hare's fur.

For the *neutria skins*, obtained from the coypou of America, the processes are nearly the same. The skin has derived its name (variously written *neutria*, *nutria*, *neutra*, *nuetra*) from the Spanish name for an otter, to whose skin it bears some resemblance. It is full of fat and grease, and requires a thorough washing with soap and boiling water before being "pulled." The outer or coarse hairs are treated like those of the rabbit and not like those of the hare; being stronger, too, they require a sharper knife and a stronger pull for their extraction. Not only the pelt side, but also the fur-side is full of grease, and need a thorough purification before the removal of the hairs and fur. When the external hair has been pulled, the inner fur is cut in the same way as the others.

The skin of the *beaver* is, in many respects, the most serviceable of them all for the hatter's purpose. It is, however, so full of grease that the pelt requires to be scoured with fullers' earth and whiting before it attains a sufficient state of cleanness. The coarse hairs are pulled out by the knife and thumb; and being of no use to the hatter, they are sold as stuffing for cushions. Then comes the cutting or cropping, which is, at the present day and in the largest establishments, effected by a very beautiful machine. There is a long broad and sharp blade, equalling in length the full width of the beaver-skin, and so adjusted as to fall rapidly with a chopping action against or near the edge of another blade beneath. The skin is placed between the two, and is attached to a piece of mechanism by which it is drawn gradually from end to end between them; as it passes, the sharp blade crops the fur from off the pelt, which it does so effectually that not a particle of fur is left behind, and yet the pelt is not cut through in any part. The fur falls down in a light flocculent layer on an endless apron beneath, from whence it is removed when the pelt is denuded. This fur is of three or four different qualities, that from the cheek being the finest and most valuable; and to separate them one from another a method at once simple and elegant is adopted. The fur is placed in a large chest or trough, where it comes within the action of a fan revolving two thousand times in a minute; the current excited by this fan is so violent that it whirls the fur along a hollow trunk or channel fifty feet in length. During the passage of the fur, the relative specific gravities of the filaments effect a separation without any farther interference: those which are largest and coarsest fall first, and are deposited on the bottom of the first compartment of the trough; those which are next heavier are deposited farther on; and lastly, the finest and best parts of the fur are blown to the extreme end of the trough, whence they can be taken without admixture with any of the others.

The cutting of the fur from the pelt by machinery has been attempted for various furs, but it has succeeded only with the beaver;

this is said to be owing to the circumstance that the beaver-pelt is very regular in thickness and uniform in surface; whereas, most of the other pelts are irregular or unequable. If the blade of the machine by passing over an irregular part of the pelt should cut off a small bit of the latter, it would be the means of spoiling the mass of fur unless removed. Attempts have been made to detach the fur from the pelt by chemical instead of mechanical means. In tanning and leather-dressing, the hair and wool of the animal are often loosened by being exposed for some hours to the action of some acid or other chemical agent: and it has been supposed that the same result would be obtained with the furs used by hatters; but it is found that, though separable by such means, the fur is injured in its felting properties—an objection fatal to the adoption of the plan.

Beaver skins have recently been brought to an excellent state for robes and other garments, by processes devised by Mr. Roberts, a London furrier. Other kinds of fur besides the four above-named are employed in hat-making, but are not so generally serviceable. *Mole fur* is fine and regular, but is almost too short to be available. *Musquash* or *musk-rat fur* is employed to some considerable extent. *Seal-fur* presents a dull appearance when worked up as a covering to a hat, being deficient in the delicate glossiness which distinguishes beaver. *Otter fur* is finer than that of the seal, and is so far more serviceable, but it does not take a good black-dye. According to the price at which a hat is intended to be sold, so is the selection of the fur employed. A good beaver hat contains in the foundation or body a mixture of fine wool with rabbit's fur, and in the covering beaver-fur alone; this is the standard, from which a departure takes place according to the price. The use of this last-named fur, however, has much lessened in recent years.

Some kinds of fur which are rather deficient in the felting property are made to undergo a process termed "carrotting," so called from the colour imparted thereby to the fur. This consists in wetting the skin (before the fur has been yet cropped from the pelt) with dilute sulphuric acid, and quickly drying it either near a strong fire or by means of a heated iron passed over it. The fur of the same species of animal often differs very much in felting quality, according to the district where the animal is found. Thus, the fur of the rabbit is said to possess a stronger felting quality when obtained from an animal reared near the sea-coast than from an inland animal; those of the eastern coast of England, from Lincolnshire to the Tweed, are considered the finest. The fur of the English hare, as a second example, is found to be both finer in quality and stronger in felting power than that of any other variety of the hare.

Dressed Furs.—By this term may be designated those furs which are retained on the original pelt, and in that state worn as garments or trimmings of garments, in the forms of cloaks, tippets, cuffs, collars, &c. Such an employment of furs was very much a matter of necessity among the rude tribes where the custom was first followed. At first the skins were worn almost in the state in which they were taken from the animals: but as the use of luxuries advanced, the art of dressing the skins became established, and fur took rank as an adornment as well as a covering.

The dressing of furs for this purpose, or *furriery*, is much more simple than the preparation of felting-fur for the hatter, since it does not involve the separation of the filaments from the pelt beneath.

The fur-hunters of America, when they have captured a beaver or other fur-bearing animal, strip off the skin, and hang it up to dry, either in the open air, or in a dry and cool room where there is no fire. Great importance is attached both to the drying and to the careful packing of the skins; for if the slightest degree of putrefaction ensues, the fur loses its firm hold of the pelt, and is not fit for furriers' purposes. When the skins are brought to England, and placed in the hands of the furrier, he examines them minutely, to see that the drying has been properly effected, and the pelt in a firm state. He then proceeds to the two processes which constitute the main part of his business, namely, extracting the greasiness from the pelt, and also a kind of oil which is in the fur itself. The skin is put into a liquid containing bran, alum, and salt; and after sufficient steeping it is worked about and scoured, so as to remove the grease. The fur is cleansed from its oiliness by an application of soda and fine soap. The cleansed skin is finally washed thoroughly in cold water, and hung up to dry. The alum and other ingredients employed in scouring the pelt effect a kind of tanning or tawing process, by which the pelt is converted into a sort of thin leather, and thereby rendered more durable.

When thus far prepared, the skins are ready to be worked up into the form of garments, or materials for garments. In order to give the surface of the fur a uniform length and colour of fibre, it is often necessary to cut up a great many skins, and sew certain pieces of each edge to edge; for it is rarely if ever the case that every part of the same skin is of one uniform colour. The cutting up of a skin thus becomes an important affair; for unless considerable tact be exhibited, many of the smaller pieces would become waste. The furs which are used for these purposes are in general different from those selected for felting; they comprise usually the gray, the silver, and the black fox, the sable, the bear, the lynx, the ermine, the mink, the chinchilla, the marten, the wolf, the fitchet, and a few others of less common character.

The preservation of furs, when kept in stock for manufacturing purposes, is a point of considerable importance, from the several sources of injury to which they are exposed. If kept too damp, they rot; if too dry, they diminish in weight. "The great enemy to all furs," says a practical writer on this subject in the 'Encyclopædia Britannica,' "is the common moth. This destroys the felting principle. Whenever the slightest appearance in the fur indicates the secure lodgment of this little creature, it ought immediately to be used; or, if this cannot be done, it should be taken out of the paper-bags, and broken all over with a small switch rod, or, what will answer the purpose still better, a hatter's bow. The same rules apply to the keeping of skins in good condition as to fur. The situation ought to be cool, dry, and well aired. They will seldom keep longer than twelve or eighteen months, without running great risk of suffering injury from the moth or black beetle. Too many ought not to be heaped together, and particularly if they be rabbit skins, because the fat or grease about these skins will get heated, run amongst the fur, and become of such an acrid nature as to corrode the very pelt itself. Many persons are inclined to keep hare and rabbit skins a long time, from a notion that the fur upon them will increase in length from the moisture left in the pelt. This is an entirely erroneous opinion. Any one who will make the experiment will find that the amount of fur obtained off any given quantity of skins is much greater in weight when manufactured immediately after they are taken off the animal, than after having been kept for six or twelve months."

FURS and the FUR-TRADE. The use of furs appears to have been introduced into civilised Europe by the northern conquerors. In the 6th century the skins of sables were brought for sale from the confines of the Arctic Ocean to Rome, through the intervention of many different hands, so that the ultimate cost to the consumer was very great. For several centuries after that time furs could not have become at all common in Western Europe. Marco Polo mentions as a matter of curiosity in 1252, that he found the tents of the Cham of Tartary lined with the skins of ermines and sables, which were brought from countries far north, from *the land of darkness*. But in less than a century from that time the fashion of wearing furs must have become prevalent in England; for in 1337 Edward III. ordered that all persons among his subjects should be prohibited their use unless their free incomes amounted to one hundred pounds a year. The furs then brought to England were furnished by the traders of Italy, who procured them from the north of Asia.

The fur trade was taken up by the French colonists of Canada very soon after their first settlement on the St. Lawrence; and through the ignorance of the Indians as to the value of the skins which they sold, and of the trinkets and other articles which they took in payment, the traders at first made very great profits. The animals soon becoming scarce in the neighbourhood of the European settlements, the Indians were obliged to extend the range of their hunting expeditions, in which they were frequently accompanied by one or other of the French dealers, whose object it was to encourage a greater number of Indians to engage in the pursuit, and to bring their peltries, as the unprepared skins are called, to the European settlements. When the hunting season was over, the Indians came down the Ottawa in their canoes with the produce of the chase, and encamped outside the town of Montreal, where a kind of fair was held until the furs were all exchanged for trinkets, knives, hatchets, kettles, blankets, coarse cloths, and other articles suited to native wants, including arms and ammunition. A large part of the value was usually paid to the Indians in the form of ardent spirits, and scenes of riot and confusion were consequently of frequent occurrence.

The next stage in the Canadian fur-trade was when some of the European settlers, under the name of *Coureurs des Bois*, or wood-rangers, set out at the proper season from Montreal in canoes laden with various articles considered desirable by the Indians, and proceeded up the river to the hunting-grounds. Here they remained for an indefinite time, sometimes longer than a year, carrying on their traffic with the Indian hunters; and when their outward investments were exhausted, they returned, their canoes in general loaded with packs of beaver-skins and other valuable peltries. While engaged in these expeditions, some of them adopted the habits of the tribe with whom they were associated, and formed connections with the Indian women. The half-caste children make excellent *voyageurs*, and are readily employed by the company in that capacity.

This trade was for some time extremely profitable. The men by whom it was conducted were usually without capital; and their investments of European goods were furnished by the storekeepers of Montreal, who drew at least their full proportion of profit from the adventure. The return cargo was generally more valuable than the investments, in the proportion of six to one, in the tariff of the Canadian markets. Thus, where the investment amounted to 1000 dollars, and the peltries returned sold for 6000, the storekeeper first repaid himself the original outlay, and usually secured for himself an equal amount for interest and commission, after which the remaining 4000 dollars were divided between himself and the Coureur des Bois.

The Hudson's Bay Company, established with the express object of procuring furs, was chartered by Charles II. in 1670, with the privilege of exclusively trading with the Indians in the vast and not well defined region lying to the north and west of the great inlet from which the company takes its name. This association founded several establishments, and has ever since prosecuted the trade under the direction of a governor, deputy-governor, and a committee of management chosen from among the proprietors of the joint-stock, and resident in London. The company's charter not being confirmed by act of parliament, it was considered that all British subjects were entitled to engage in the trade with those regions; and, in conformity with this notion, a partnership was formed in 1783 under the name of the North-West Company, which proved a powerful competitor. This company consisted of twenty-three shareholders or partners, comprising some of the most wealthy and influential British settlers in Canada, and employed about 2000 persons as clerks, guides, interpreters, and boatmen or *voyageurs*, who were distributed over the face of the country. Such of the shareholders as took an active part were called agents; some of them resided at the different ports established by the company in the Indian territory, and others at Quebec and Montreal, where each attended to the affairs of the association. These active partners met once in every year at Fort William, one of their stations near the Grand Portage on Lake Superior, in order to discuss the affairs of the company and agree upon plans for the future. The young men who were employed as clerks were, for the most part, the younger members of respectable families in Scotland, who were willing to undergo the hardships and privations accompanying a residence for some years in these countries, that they might secure the advantage of succeeding in turn to a share in the profits of the undertaking: the partners, as others died or retired, being taken from among those who, as clerks, had acquired the experience necessary for the management of the business. This company had a settlement, called Fort Chippewyan, so far west as the Lake of the Hills, in 110° 26′ W. long.; and some of the Indians who traded with the persons stationed at this fort came from beyond the Rocky Mountains.

A great degree of jealousy and hostility arose between the respective agents of the Hudson's Bay and North-West companies, which more or less impeded the operations of both parties for several years, until in 1821 a junction of the two was effected, and the trade has since been prosecuted peacefully and successfully. Their presumed exclusive right of trading throughout the vast region which they have made the scene of their operations, is still guarded with extreme jealousy, as we shall see further on. All the furs collected by the Hudson's Bay Company are shipped to London,—some from their factories of York Fort and Moose River, in Hudson's Bay; other portions from Montreal; and the remainder from the Columbia River.

The fur-trade is prosecuted in the north-western territories of the United States by an association called the North American Fur Company, the principal managers of which reside in New York. The chief station of this company is Michilimackinac, to which are brought all the peltries collected at the other ports on the Mississippi, Missouri, and Yellowstone rivers, and through the great range of country extending thence to the Rocky Mountains. This company employs steam-boats for ascending the rivers, which penetrate with ease to regions which could formerly be explored only through the most painful exertions in keel-boats and barges, or by small parties on horseback or on foot.

We shall here notice a few of the principal fur-bearing animals, referring the reader to the NATURAL HISTORY DIVISION for more specific information.

The *ermine*, called by way of pre-eminence "the precious ermine," is found almost exclusively in the cold regions of Europe and Asia. The *stoat*, which in fact is identical with the ermine, but the fur of which is greatly inferior to that of the European and Asiatic animal, is found in North America. The fur of the ermine is of a pure whiteness throughout, with the exception of the tip of the tail, which is black; and the spotted appearance of ermine skins, by which they are peculiarly known, is produced by fastening these black tips at intervals on the skins. The animal is from 14 to 16 inches long from the nose to the tip of the tail, the body being from 10 to 12 inches long. The best fur is yielded by the oldest animals. They are taken by snares and in traps, and are sometimes shot, while running, with blunt arrows. The *sable* is a native of Northern Europe and Siberia. The skins of best quality are procured by the Samoids, and in Yakutsk, Kamtchatka, and Russian Lapland: those of the darkest colour are the most esteemed. The length of the sable is from 18 to 20 inches. It has been considered by some naturalists a variety of the pine-marten. *Martens* are found in North America as well as in Northern Asia and the mountains of Kamtchatka: the American skins are generally the least valued, but many among them are rich and of a beautiful dark-brown olive colour. The *fiery fox*, so called from its brilliant red colour, is taken near the north-eastern coast of Asia, and its fur is much valued, both for its colour and fineness, in that quarter of the world. *Neutria* skins are obtained from South America, and the greater part of the importations in this country come from the states of the Rio de la Plata. These skins are of comparatively recent introduction; having first become an article of commerce in 1810: the fur is chiefly used by hat-manufacturers, as a substitute for beaver. *Sea-Otter* skins were first sought for their fur in the early part of the 18th century, when they were brought to Western Europe from the Aleutian and Kurile Islands; where, as well as in Behring's Island, Kamtchatka, and the neighbouring American shores, sea-otters are found in great numbers. The fur of the young animal is of a beautiful brown colour, but when older the colour becomes jet-black. The fur is exceedingly fine, soft, and close, and bears a silky gloss. Towards the close of the 18th century furs had become exceedingly scarce in Siberia, and it became necessary to look to fresh sources for the supply of China and other Asiatic countries. It was about the year 1780 that sea-otter skins were first carried to China, where they realised such high prices as greatly to stimulate the search for them. With this view several expeditions were made from the United States and from England to the northern islands of the Pacific and to Nootka Sound, as well as to the north-west coast of America. The Russians then held and still hold the tract of country most favourable for this purpose, but the trading ships which frequent the coast are enabled to procure these skins from the Indians. *Fur-seals* are found in great numbers in the colder latitudes of the southern hemisphere. South Georgia, in 55° S. lat., was explored by Captain Cook in 1771, and immediately thereafter was resorted to by the colonists of British America, who conveyed great numbers of seal skins thence to China, where very high prices were obtained. The South Shetland Islands, in 63° S. lat., were greatly resorted to by seals, and soon after the discovery of these islands in 1818, great numbers were taken: in 1821 and 1822 the number of seal skins taken on these islands alone amounted to 320,000. Owing to the system of extermination pursued by the hunters, these animals are now almost extinct in all those islands, and the trade for a time at least has ceased. The seal-fishery, or hunting, in the Lobos Islands, is placed under restrictive regulations by the government of Montevideo, and by this means the supply of animals upon them is kept pretty regular. *Bears* of various kinds and colours, many varieties of *foxes, beavers, racoons, badgers, minks, lynxes, musk-rats, rabbits, hares,* and *squirrels*, are procured in North America. Of all the American varieties, the fur of the *black fox*, sometimes called the silver fox, is the most valuable; next to that in value is the fur of the *red fox*, which is exported to China, where it is used for trimmings, linings, and robes, which are ornamented in spots or waves with the black fur of the paws of the same animal. The fur of the *silver fox* is also highly esteemed. This is a scarce animal, inhabiting the woody country below the falls of the Columbia river. It has long thick fur of a deep lead colour, intermingled with long hairs white at the top, forming a lustrous silver-gray, whence the animal derives its name. The hides of *bisons* (improperly called buffaloes), of the *sheep* of the Rocky Mountains, and of various kinds of *deer*, form part of the fur-trade of North America; and sometimes the skin of the *white Arctic fox* and of the *Polar bear* are found in the packs brought to the European traders by the most northern tribes of Indians. There is but one species of fur which is peculiar to England, the *silver-tipped rabbit* of Lincolnshire. The colour of the fur is gray of different shades, mixed with longer hairs tipped with white. This fur is but little used in England, but meets a ready sale in Russia and China; the dark-coloured skins are preferred in the former country, and the lighter-coloured in China.

The fur-sales of the Hudson's Bay Company are held every year in the month of March, and being of great magnitude, they attract many foreign merchants to London. The purchases of these foreigners are chiefly sent to the great fair at Leipsic, whence the furs are distributed to all parts of the continent of Europe.

Circumstances of a remarkable kind have recently given a new interest to the American fur-trade, in relation to its political, proprietary, and commercial aspects. In the articles HUDSON'S BAY TERRITORIES, OREGON, and VANCOUVER, in the GEOGRAPHICAL DIVISION of this Cyclopædia, an account is given of the mode in which the Hudson's Bay Company's operations received an extension on the coast of the Pacific. Since the period when those articles were published, important events have occurred which call for some notice here, seeing that they are likely to affect the future course of the fur-trade.

In 1856 gold was discovered on the banks of Fraser River, within a short distance of Vancouver Island, about 800 miles north of San Francisco, in California; and in 1857 the discovery was amply confirmed. The region belonged to England, but had been only interesting to Englishmen in so far as the Hudson's Bay Company had established fur-hunting stations upon it. Now, however, a new order of things commenced. If the gold were at all plentiful, it was certain to attract a large number of diggers from California, and adventurers from other quarters, and to bring about a state of society with which the company's servants would be incompetent to deal. The company have uniformly discouraged trading and colonising by any free trading community, in order to retain the monopoly of the fur-trade in their own hands. When the island of Vancouver was leased to them by the Crown, there was a virtual undertaking by them to colonise it; a condition which, though not actually evaded, has been but ill-fulfilled. A town, called Victoria, was established on the island; and this became the head-quarters of the company's operations in that region. The island is little more yet than an uncleared forest, with 20,000 aboriginal inhabitants and a small number of Europeans. Victoria has many of the elements for a magnificent port; it was a mere hamlet of 400 souls when the gold discovery was made; but it was speedily overrun by 6000 or 8000 adventurers, who came to it from all quarters as the nearest town to the gold-fields. Fortunately, Mr. Douglas, the chief officer, was a man of tact and energy, and proved himself equal to the difficulties of his new position. It must be understood that the company had no governing power in the island; they held a lease of the soil for ten years (1849 to 1859) for trading purposes, on condition of establishing a colony and disposing of land to emigrants; but the governor was appointed by the Crown, and legislative houses were chosen by the people. The company as well as the government felt that such an important island could not long remain in this anomalous condition; for it has all the capabilities for being a great naval station for British ships on the eastern margin of the Pacific, and is moreover very advantageously situated for commerce. It had become well understood that the lease to the company would not be renewed in 1859; but the gold discoveries on the adjacent coast rendered additional arrangements necessary. In July 1858 the government brought a bill into the House of Commons for the establishment of a new colony to be called New Caledonia, to comprise the island of Vancouver and a wide stretch of the adjacent mainland. This mainland portion extends from the Pacific to the Rocky Mountains, about 300 miles; and from latitude 49° N. to about 55°, a little over 400 miles. No governor or magistrate of any kind existed within those limits, for Mr. Douglas only governed the island; and therefore speedy legislation became necessary, to prevent anarchy, and to secure the region to the British crown. The act proposed by the bill was to endure only until 1863, to afford an opportunity for modification in the governmental regulations. With a few amendments and alterations the bill became a law (21 & 22 Vict. c. 99); but the name of the colony was changed from New Caledonia to British Columbia. A disagreement with the United States Government, in 1859, did not affect the general ownership of this new colony, but only referred to the small island of St. Juan, which is claimed by both nations, owing to a want of clearness in a treaty which settles the boundary in those regions at the 49th parallel of north latitude. The eventual colonisation of British Columbia will interfere a little with the fur-hunting arrangements of the Hudson's Bay Company; but it will exert still more influence by introducing the principles of unshackled trade into a region where strict monopoly has hitherto been maintained. There seems a probability, also, that the fur-trading privileges of the company in other quarters will shortly be curtailed; the wishes of the legislature in this respect were pretty strongly expressed in 1858 and 1859, in reference to certain licence-privileges terminable in 1860.

A committee of inquiry, appointed by the House of Commons in 1857, was the means of bringing to light much curious information concerning the fur-trade. Occurring before the events just noticed were fully known, the inquiries could not bear relation to the gold deposits, nor to the new political relations of the western coast; but as far as concerns the fur-trade, the information remains as true in 1860 as it was in 1857. This is the more valuable, because the company have always been very chary of communicating information concerning their commercial transactions; on this account, a few facts may suitably be introduced here.

The company's vast territories are ruled by a governor-in-chief, invested with large powers. For forty years this office has been held by Sir George Simpson. Under him are sixteen chief factors, controlling districts or provinces into which the territories are divided. Subordinate to these are twenty-five chief traders. Each factor or trader has a sort of metropolis or head-quarters, called a fort, factory, or post, large enough to accommodate a considerable number of persons, and strong enough to be defended against any hostile attacks by Indians. The chief factors and chief traders are not salaried servants; they are partners or shareholders, receiving, in return for their personal services, a definite percentage on the company's annual trading net profits. Under the factors and traders, or associated with them, are five surgeons, forty chaplains or missionaries (belonging to four Christian denominations), about a hundred and fifty clerks and postmasters or messengers, and twelve hundred servants or subordinates. Nearly all these persons receive their appointment from the directors of the company, and a large number of them are Orkney men. They go out at first under an engagement for five years; but most of them stop much longer, some as long as twenty-five or thirty years, and the average as many as fifteen. The first wages for servants, labourers, &c., is about 20*l.* a year, besides board, lodging, and other necessaries; and the men gradually rise in station and in salary according to their ability. The chief factors, with the governor-in-chief, constitute the members of a council, which meets annually in June, to review the whole events of the past year, and to make arrangements for the year next ensuing. If the factors from the more distant stations cannot conveniently come to make up a *quorum* of seven or eight, a few of the chief traders are admitted to complete the number. The governor-in-chief and the council of factors bear some such relation to the Hudson's Bay Board in London, as the governor-general and supreme council of India bore to the board of directors in the old East India Company; there are certain general rules and orders sent out from home, but a wide discretion is left in the application of them.

So much for the relations between the company and their white servants; those with the natives bring us at once to the present mode of managing the fur-trade. Besides the persons already mentioned, the company employ five hundred *voyageurs*, to manage the canoes on the rivers and portages; and an indefinite number of persons as servants, labourers, hunters, fishers, and assistants generally, just as their services are wanted. Nearly all these persons are Canadians or Europeans; or they are half-breeds, descendants of white men and native women. The Indians, the natives proper, are not servants of the company; they kill the animals, and bring the skins and furs to the trading posts; but each one is an independent trader, bartering and bargaining for himself. The independence is, however, a peculiar one. During the summer months the Indians work for the company at any odd jobs, if willing, and if their services are needed: but when winter is coming on, they set off to the hunting-grounds. Being poor and improvident, they have nothing to set out with; the company give them blankets, guns, and ammunition, which are to be paid for in the following spring, each article being valued at so many beaver-skins. During the winter they obtain what furs they can. The company do not inform them what kinds are most highly valued, or bring most money, in England. Dr. Rae, the enterprising Arctic explorer, and one of the most energetic of the company's servants, said in evidence before the committee:—"The company's tariff with the Indians is formed in a peculiar way, and necessarily so. The sums given for furs do not coincide with the *value* of the furs traded for; because the musk-rat, or the less valuable furs, are paid for at a higher [proportionate?] rate. Were the company to pay for the fine furs at the same rate, the Indians would hunt up the finer furs, and destroy them off, as has been done all along the frontier of America; and we should require to reduce the price for the musk-rat and the inferior furs, and the Indians would not hunt them at all. The Indians would never understand our varying the prices of the furs according to the prices here (in England)." The meaning of this is, that the company, by giving a comparatively high price for common furs, realise only a small profit thereon; but they get an enormous profit on the best furs, such as the beaver and the silver fox; and it may be doubted whether their motive is altogether so disinterested as is stated, in concealing the European estimate of furs from the knowledge of the Indians. These Indians would gladly obtain ardent spirits in barter for furs; but the company have wisely forbidden this, except in a few frontier districts, where the company have to compete with the Americans, who entertain no such scruples. The company send out yearly about 60,000*l.* worth of blankets, cloth, guns, ammunition, knives, and miscellaneous articles; of which about one-third is for the use of the company's servants, and two-thirds for barter with the Indians for furs. Money is never paid for the furs, except near the frontiers, where competition exists. The Indians mostly live upon fish and buffalo; all their other necessaries (and luxuries) they obtain from the company by bartering furs. Beads, needles, thread, and numerous small articles, are kept at the trading posts, not for barter, but as presents to retain the good will of the natives. The company are *nursing* the northern half of their territories: that is, encouraging the hunters to bring in the cheaper and more plentiful furs, instead of exhausting the stock of those which are scarcer and more valuable; as a consequence, the whole stock and the whole trade have been gradually becoming more valuable between 1840 and 1860. An average beaver-skin is the standard of currency between the company and the hunters; European articles are worth so many "beavers" each. A sort of tariff was agreed upon many years ago, and is only in a slight degree altered, once now and then. The company are virtually the makers of this tariff, for they sedulously keep the Indians in ignorance of the relative values of furs in Europe. Ten musk-rats equal one beaver; so many beavers equal one silver-fox; &c. But when we come to compare English goods with Indian furs, the nature of the company's profit peeps out. A blanket equals "four beavers;" a gun (bought at Birmingham for 22*s.*) is equal to "twenty beavers;" a slop-made coat is equal to "five or six beavers." A gun, in consideration of the relative high price given for inferior skins, may sell for only 4*l.* or 5*l.* in musk-rats; but estimated in silver-foxes, it sometimes brings 50*l.* worth—a startling profit on a cheap Birmingham gun. Beaver fur has varied in price, during the last few years, from 8*s.* to 30*s.* per lb. in the London market: an average skin yielding about 1 lb. of fur; so that the company's profits vary greatly, seeing that the Indian tariff does not vary with the London prices. Moreover, it is asserted by the company, as a drawback on their apparently excessive profits, that a period varying from three to seven years elapses before capital can be returned: that is, between the time at which goods are bought in England, and the time at which the furs are sold in England which have been procured by bartering those goods—so extremely slow and tedious are all the operations in the wide-spreading and thinly-inhabited territories of the company. It is undisputed, however, that the company's profits from the fur-trade are quite out of the line of ordinary commercial transactions; and if the statements of many writers on the subject are to be received as correct, the profits are quite enormous. Lieutenant Chappel, some years ago, estimated the profits at 2000 per cent. The Rev. C. G. Nicholay, in his 'Oregon Territory,' says, "A fourpenny comb will barter for a bear's skin worth 2*l.*" Dr. King; in his 'Arctic Narrative,' says, "A coarse knife, worth, all expenses included, no more than sixpence, is bartered for three marten skins, worth in London five guineas; and for the skin of the black sea otter, worth fifty guineas, the natives obtain in exchange only goods to the value of two shillings."

It is believed by competent authorities, that even if the fur-trade were thrown open, a long time would elapse before the trading of the company would cease to hold its prominence: because of the wide ramifications of their system, and because also of the ties of various kinds which bind the native hunters to them. There are not many furs procured from Vancouver.

Concerning the quantity of furs and skins brought to England, the official returns are not quite clear, seeing that sheep and goat skins are combined in the same entries as those which we are more in the habit of denominating furs. The Hudson's Bay Company, during the last five years, have imported about 700,000 skins annually. Only a small number are sold for consumption in England; the greater part is bought up by foreign merchants, who come to London for that purpose; or rather, they are purchased and partially prepared in England, and then sold to foreigners, especially the merchants of Leipsic. Our total imports from all quarters nearly reach 4,000,000 skins annually, of which 400,000 are racoon and 600,000 seal; the greater portion of the remainder comprises weasel, marten, beaver, neutria, musk-rat, rabbit, and squirrel skins. It is roundly estimated that the *retail* value of all the furs put to use annually in all parts of the world cannot be much less than 7,000,000*l.*, of which one-third is produced by Russia.

Taking one particular year, 1856, we may usefully, in addition to the number of furs imported, quote the average prices assigned by the importers in computing the real values.

	No.		Average Price.
Bear	11,870		£2 4 0
Beaver . . .	82,830		0 9 6
Coney . . .	142,285		0 0 4

FUSCOBALTIA. [Cobalt, *ammoniacal compounds of cobalt.*]

FUSE is a tube filled with a peculiar combustible composition. Fuses are principally used in firing shells. They are made in such a manner, that either by cutting or boring, or adjusting as in the fuse used in Sir W. Armstrong's gun, the length of the composition may be proportioned to the intended range of the shell, so as to burst the shell when it strikes the object, or before if required. The common wooden fuse is made of well-seasoned beech-wood in the form of a slightly tapering cylinder, with an enlargement at the larger end. The cylinder is pierced by a bore of ¼ inch in diameter, which terminates in a hemispherical cup in the enlargement. The bore is *driven* with fuse composition consisting of nitre, 3 lbs. 4 oz.; sulphur, 1 lb.; mealed powder, 1 lb. 12 oz.; which is hammered in hard by the hand, and then burns at the rate of ·2 inches per second. The cup is primed with quick match, in order to be easily ignited by the explosion of the shell. The exterior of the wooden cylinder is marked with rings ¼ inch apart, so that by sawing off a piece or by boring out the composition from the lower end it can be made of any length required; the fuse is then fixed in the shell by gently hammering it in. For sea service metal fuses are employed. They are made of gun-metal of the same shape as the wooden ones, but are screwed into the shell, which is fitted with a gun-metal collar to receive them. They cannot be cut or bored to any particular length, as it is not considered safe to do so on board ship, but are made of three lengths, 4, 3, and 1½ inches, which burn 20, 7½, and 2 seconds. The priming is protected by a metal cap which is unscrewed when required.

The old wooden fuse has been nearly superseded by one invented by Captain Boxer, R. A. a few years ago. The external form is much the same, but the bore is slightly eccentric, and parallel to it; two much smaller bores or channels are made in the thicker side of the wood. These small bores contain quick match, and fine grain powder, which communicate with the fuse composition at the bottom. Small holes ·2 inches apart are made from the exterior to the bore containing the quick match and fine grain powder, and are filled up again with putty. By boring through the putty and the wood between the channel containing the fine grain powder and the fuse composition, these two are put in communication as it were, and when the composition has burned down to that point in the fuse, the flame drives through the hole, lights the powder and the charge of the shell at once. The small holes are bored at ·2 of an inch apart, those in one row being opposite the blanks of the next, so that the fuse can be adjusted to tenths of an inch, with much greater ease and precision than with the old fuse. Boxer's fuse also has the advantage of being solid at the end, the bore with composition not running the whole length, hence there is no chance of the composition being driven through by the concussion of the discharge. Sir W. Armstrong, by a very beautiful arrangement, which it would take too long to describe here, has made his fuse so that without removing it from the shell, by turning a dial-marked plate at the top which carries the composition in a circular ring, any portion of this ring is brought opposite a channel of fine grained powder, which communicates with and fires the charge of the shell.

FUSEE. [Horology.]

FUSEL OIL. The oils which contaminate potato and grain spirit are classed by the Germans under the common name *fuseloel*, and the same term translated is applied by English chemists to these oils. Potato spirit is accompanied by the hydrated oxide of amyl, or oil of potato spirit [Amyl], whilst grain spirit is accompanied by an oily matter consisting of margaric, capric, and œnanthic acids, which probably, with the spirit, form their corresponding ethers. Dr. Gregory suggests that this is probably the composition of the oil of grain, the *Oleum siticum* of Professor Mulder.

FUSIBLE METAL. An alloy of 5 parts of bismuth, 2 of tin, and 3 of lead, melting about the temperature of boiling water. It is used for stereotype plates, and for the blocks of calico printers. [Bismuth].

FUSION. The different temperatures at which certain solids are rendered fluid have been already mentioned. [Freezing Points.] In addition it may be merely remarked that fusion is sometimes used with the prefix of *watery*, and at other times *igneous*. Watery fusion is that which occurs when a salt, such as sulphate of soda for example, containing much water of crystallisation, fuses or melts in its water by exposure to a moderate heat; it may afterwards undergo igneous fusion by exposure to a much higher temperature.

FUSTIAN is a kind of cotton fabric similar in the mode of manufacture to velvet, having in addition to the warp and weft common to all woven goods, a *pile* consisting of other threads doubled under the weft, and thrown at intervals so close together that when the goods are finished the interlacing of the warp and weft are concealed by them. [Velvet.] While in the loom the pile forms a series of loops, which are afterwards cut and sheared. The cutting is performed by running a knife through each series of loops as they occur in the weft; this gives an uneven and hairy appearance to the cloth, which is afterwards remedied first by the shearing process, and afterwards by singeing and brushing—which latter operations are repeated until the fustian has acquired a smooth and polished appearance. The shearing of fustians is a separate art, employing many thousand persons in Lancashire. Until lately the operation of fustian-cutting was conducted by hand; but the aid of machinery has now been obtained; and instead of the tedious operation of cutting open only one set of loops at once, a series of knives are brought to act together and continuously, until the whole piece is finished. By this means the work is not only done more quickly, but is also better performed than when its excellence depended upon the uniform precision of the human hand.

Various kinds of fustians are made, and are known by different names, according to their form and fineness. The best kinds are known as cotton velvet and velveteen; besides these there are beaverteens, moleskin, corduroy, and cords. Different patterns are produced by different dispositions of the pile threads. Fustians are woven both in the hand-loom and with the power-loom; they are made of different widths, some pieces being 18 and others 27 inches wide: a piece of velveteen of medium quality, 90 yards long and 18 inches wide, weighs about 24 or 25 lbs. The yarn for the warp is made of New Orleans cotton, or of Upland Georgia and Brazil cotton mixed, of the fineness of 32 hanks to the pound; the weft and pile are usually spun from Upland mixed with East India cotton, and the yarn is commonly of the fineness of 24 hanks to the pound. For further illustrations, see Cotton Manufacture; Velvet; Weaving.

FUSTIN. The non-azotised yellow colouring matter of fustic. Its composition is not known.

FUTURE. [Conjugation; Time.]

G

G. This letter is derived from the Latin alphabet, in which it first appears. In the Greek alphabet its place is supplied by *zeta*. If, as seems probable, the sound of this Greek letter was the same as the consonantal sound at the beginning of the word *judge* (see Z), it may perhaps be inferred that the hissing sound now given to the letter *g* existed already in some dialect of ancient Italy. The sound at any rate is familiar to the modern Italian. The sound of the letter *g* in the English language is two-fold. Before *a*, *o*, and *u*, and occasionally before *i* and *e*, it is the medial letter of the guttural order. The other sound, which it possesses only before *i* and *e*, is one of the medials of the sibilant series, and is also represented by the letter *j* as pronounced by the English. [ALPHABET, col. 234.] The sibilant sound is written in Italian by two letters, *gi*, as Giacomo, Jacob, or by *gg*, as *oggi*, to-day. The two-fold nature of the sound corresponds to the double sound of the letter *c*, which is sometimes a *k*, sometimes an *s*. [See C.]

The guttural *g* is liable to many changes in different dialects or languages.

1. *g* and *k* are convertible. Thus the Greek and Latin forms genu, *γονυ*; gen, *γεν*, as seen in gen-us, *γεν-ες*, *gi-g(e)n-o*, *γι-γ(ε)ν-ομαι*; *gnosc*, as seen in *gnosc-o*, *γι-γνωσκ-ω*—severally correspond to the German and English *knie*, *knee*: *kind*, *kin*.

2. *g* and an aspirated guttural: as, Greek, *χην*; German, *gans*; English, *goose* and *gander*. Perhaps *χαινω* may be related to the German *gaffen* and English *gape*. There can be no doubt as to the connection between the Greek *χθες*, the Latin *hes-ternus*, and the German *ges-tern*. The close connection of the two sounds may also be seen in the pronunciation of the final *g* in high German like *ch*, as *Ludwig*, &c.

3. *g* and *h*. As the letter *h*, when pronounced at all, is only a weak aspirate, this interchange strictly belongs to the last head. As an additional example, we may refer to the Latin word *gallus*, which has all the appearance of being a diminutive, like *bellus*, *ullus*, *asellus*, from *benus*, *unus*, *asinus*. If this be admitted, the primitive was probably *ganus*; and we see its corresponding form in the German *hahn*, a cock.

4. *g* often disappears: First, at the beginning of a word, as in the Latin *anser*, a goose, compared with the forms given above, and in the English *enough* compared with the German *genug*. A large number of examples of this may be seen in the poetical participles of the English language, commencing with a *y*, as *yclept*, *yclad*, &c.; also in *ago* for *agone*; in all of which the fuller form began with *ge*, as is still seen in German. The loss of *g* is particularly common before *l* and *n*, as Eng. *like*, Germ. *gleich*; Lat. *nosco*, *nascor*, *nitor*, from *gnosco*, *gnascor*, *gnitor*. Secondly, in the middle of words between vowels. This may be seen in French words derived from the Latin, as: *legere*, *lire*, read; *magister*, *maistre*, master; *Ligeris*, *Loire*, &c.; also in English words connected with German, as *nagel*, *nail*; *segel*, *sail*; *regen*, *rain*, &c. In such cases the vowel is generally lengthened. Lastly, at the end of words, as, *sag-en*, *say*: *mag*, *may*; *tag*, *day*; here again the syllable is strengthened.

5. *g* and *y* are convertible; as, *yester-day*, compared with the Germ. *gestern*; *yawn* with *gähn-en*; *yellow* with *gelb*. In our own language we find related words showing this difference: *yard* and *garden*; *yate*, a dialectic variety of *gate*; *yave* for *gave* (Percy's 'Reliques,' i. p. 294, note); and *yode*, a perfect of *to go* (Glossary of same).

6. *g* is convertible with *gu* and *w*. In the Latin language there co-exist the forms *tinguo*, *tingo*; *unguo*, *ungo*; *urgueo*, *urgeo*, &c. In the French language *gu* is presented to the eye, but *g* to the ear, in the following: *guerre*, *guêpe*, *guarder*, &c.; while in English we have *war*, *wasp*, *ward*, or *guard*. Under this head it may be observed, first, that a final *w* in the English language often corresponds to a guttural in other Teutonic dialects, as *saw*, *raw*, *crow*, *row*, *maw*, &c.; secondly, that we often have two letters, *ow*, where the German has a guttural g, as *follow*, *sorrow*, *morrow*, *furrow*, *gallows*, *marrow*, *borrow*, *barrow*.

7. *g* and *b* interchangeable. This is generally confined to those cases at the beginning of words, when an *r* or *l* follows, as in the Æolic forms, *γλεφαρον*, *γληχων*, *γαλανος*, in place of *βλεφαρον*, *βληχων*, *βαλανος*. Hence the Latin *glans*. So the Turks have given to Prussia the name of *Gharandaberk*, that is, *Brandenburg*. This change of a guttural to a labial is more intelligible, where a syllable originally commencing with such letters as *gu* or *gou* has subsequently appended to it a syllable which contains a weak vowel, *e* or *i*. By such addition there is produced the vowel assimilation which the Germans call *umlaut*, but at the same time a small remnant of the original vowel-sound is retained in the form *w*. Thus *gouz-out* in Breton is an infinitive signifying to know, connaître. The suffix of the first person of the future is *inn*, the effect of which is to modify the base *gouz*, so as to produce the form, *gwéz-inn*, je connaîtrai, and in a compound, *ana-véz-inn*, je reconnaîtrai. Here the *g* wholly disappears, and we have in its place a lip-letter *v*. Such a change is of repeated occurrence in Breton: and it is on this account that our example has been taken from this outlying language. We have, however, an example of a similar influence in English, where *good*, Germ. *gut*, on receiving the comparatival suffix *er* passes through some such form as *gwetter*, and becomes eventually *better*.

8. *g* and *d*: as *δη-μητηρ* for *γη-μητηρ*. Examples of this interchange may be heard from the mouth of nearly every child in its first attempts to speak, as *Dy Flot* for *Guy Fawkes*, *dood boy*, *do away*, &c. This change, as in the last case, is common before *l*; hence the Latin *dulcis* by the side of the Greek *γλυκυς*.

9. The guttural *g* and the sibilant *g*. It was stated in C that the hard sound of that letter in the Western languages of Europe often corresponded to a hissing sound in the Eastern. So too the hard *g* belongs to Europe, the *j* sound to Asia. Thus *rey*, a king, is in the East *rajah*.

10. The sibilant *g* and *di* or *bi* before a vowel. For examples, see D and B.

GABION. A hollow cylindrical basket open at both ends. They were formerly made of different dimensions, according to the service for which they were to be employed; they are now, however, all made of one size in the British service, namely, 2 feet in diameter (exterior), and 2 feet 9 inches high in the wicker-work. They are constructed in the following manner:—A circle of 22 inches in diameter is traced on the ground, each quarter of this circle is divided into 4 or 5 parts, according to the suppleness or stiffness of the *withes* to be used in *wailing* this basket work; at each of these points upright pickets 3 feet 6 inches in length are driven. The wicker-work which then follows may be either performed with two rods, called *pairing*, or with three or more, called *wailing*; all that is requisite is that each rod should be successively twisted over and outside those before it, passing as many pickets or stakes as there are rods to be waled, before being brought inside. Fresh rods are introduced as fast as each rod used in wailing comes to an end, and they should not be all of one length to terminate together; each layer is hammered down tight on the one preceding. When the wicker-work has risen to the height of 2 feet 9 inches, the whole is stitched together with rope yarn or twisted withes, the gabion pulled up and the pickets cut off and pointed at a length of 3 inches on each side beyond the wicker-work. Gabions are used in the revetment of field works, SAPS, PARAPETS, BATTERIES, &c.; they are then placed on end, the earth from the excavation thrown into them, when they act as a *retaining* wall to the earth which is thrown over and in front of them. When the height of the parapet requires it, two rows of gabions are placed one over the other, generally with a line of fascines between, the whole being terminated with three rows of fascines placed pyramidally, that is, two as a base and one at top, the revetment having a slope of 3 inches in 2 feet to the front. The weight of a gabion varies much according to the density of the wood from 20 to 40 lbs., and upwards; in fact, like many other points in military art, this requires great forethought. In the West Indies, after gabions had been made of the usual size for the attack of a post, they were found so heavy that it was impossible to carry them.

There is another description of gabion termed *sap roller*, used in sapping. The sap roller consists of two gabions each 6 feet long, the larger one 4 feet in diameter, the smaller 2 feet 8 inches, both strongly made, fastened together, the smaller inside the larger, and the interval filled with faggots or pickets of strong wood, so as to be musket proof. This is used in pushing on in front of a sap as a mantlet. [SAP.]

During the siege of Sebastopol it was found difficult to procure brushwood to make gabions, and Major Elphinstone, R.E., proposed using the iron hay-bands (hoop iron) employed in packing the compressed hay instead of the withes; these were tried and found of great service, not so liable to be destroyed by the explosion of guns when used in the revetment of embrasures, &c. Since then this idea has been further developed by Captain Tyler, R.E., whose gabion has been adopted to a certain extent in the service. This gabion consists of a plate of thin galvanised iron, which, when required to serve as a gabion, is formed into a cylinder by being sewn together by eyes provided for the purpose at its edges, but which, from lying flat, is easily carried. It is doubtful, however, whether a square gabion of sheet iron would not answer all purposes better.

GABLE, the triangular upper part of the end wall of a building, corresponding to the sloping sides of the roof which terminates in it. The acuteness of the angle depends therefore on the pitch of the roof, and differs considerably in different examples. Formerly the entire end of the building of which the gable is a part was not uncommonly termed the gable, but it is now more commonly called the gable-end. The term gable is not used in classical architecture, the place of the gable being occupied by the pediment. In Elizabethan domestic architecture, the open ornamental terminations of projecting wings, &c. are called gables, though they have no connection with the roof; false gables are not uncommon in Italian ecclesiastical architecture.

In ecclesiastical architecture of the Romanesque and pointed Gothic periods the gables are very important features. In our own country, church gables of the Norman and Early English periods are usually finished with a flat or moulded coping at the sides; and frequently terminated with a cross or finial at the apex. Sometimes in rich Early English and Decorated examples crockets are carried up the coping. Gables of Decorated and Perpendicular date, sometimes have a parapet, either plain, pierced, panelled, or battlemented. In old English secular architecture also, the gable was made a highly decorative feature either constructively or by the addition of ornamental barge-boards. [BARGE-BOARD.] Numerous examples of all the kinds of gables here referred to will be found in Messrs. Brandon's 'Parish Churches,' and Paley's 'Ornamental Gables.' For examples of some of the many varieties of Elizabethan gables see ELIZABETHAN ARCHITECTURE. In some English houses of the time of Elizabeth and James I., and commonly in old Scottish and continental buildings (especially those of Flanders, Holland, and Germany) the sides of gables are formed like a series of steps: these are known as *stepped-gables*, in Scotland they are termed *corbie-steps*. The small gable-like ornaments over niches, on buttresses, &c., in Gothic architecture are called *Gablets*: see examples under BUTTRESS, col. 472.

GADUIN. A brown matter said to be contained in cod-liver oil. Its composition is unknown, and its existence as a distinct compound very doubtful.

GAEL, GAELIC. Although the language spoken by the Scottish Highlanders is familiarly known among the Lowlanders by the name of the *Erse*, or, according to the more usual pronunciation, the *Ersh*,—that is, plainly, the Eirish or Irish,—the people themselves are never called by that name. Among the Highlanders the name Erse is unknown, either as that of the nation or of the language. They call themselves only the *Gadhel*, also sometimes written and always pronounced *Gael*; and their language the *Gaedheilg*, pronounced *Gaeilg*, or, nearly, *Gaelic*. The name *Gaelic* is also in familiar use among the Lowlanders as that of the language. Further, the only name by which the Irish are known to the Scottish Highlanders is *Gael*; the latter call themselves *Gael Albinnich*, or the Gael of Albin, and the Irish *Gael Erinnich*, or the Gael of Erin. The Irish also call themselves the *Gadhel*, or *Gael*; and their language the *Gaelic*. Finally, the Welsh call the Irish *Gwyddel*, which is evidently the same word with *Gadhel*, or *Gael*.

This is nearly all that can be stated as matter of fact in regard to the name *Gael*. The rest is all speculation and conjecture; of that, however, few words have given rise to so much. We shall not here attempt to do more than to indicate and arrange the various points as to which many volumes of philological and historical controversy have been written.

It has been generally assumed and admitted that the modern Gael are a portion of the *Galli*, or Gauls, of antiquity, the people who gave its former name to the country now called France, and who were principally, though by no means exclusively, known to the Greeks and Romans as the inhabitants of that region. This opinion has been adopted upon the grounds of the similarity of the two names,—some historical and traditional testimony to the fact that South Britain was originally peopled from Gaul,—some traces, rather faint and disputable, of identity of institutions and customs,—and, what would be the strongest argument, if it were well made out, the evidences of identity of language conceived to be established by the comparison of the names of places in France, and a few other remains of the old language spoken there, with the modern Gaelic of Scotland and Ireland. The Rev. Archdeacon Williams, in an essay printed in the 'Transactions of the Royal Society of Edinburgh,' vol. xiii., has been the strongest supporter of this theory, and maintains that the Galli Veteres, or Umbrians, of the Romans, the inhabitants of Gallia Cisalpina, were of the Cumic or Cymric races; that their language "formed some portion of the non-Hellenic elements of the Latin tongue; that the race was cognate with the Cymri of Wales, and that they were Celts, and not Germans."

Supposing the Gael to be the *Galli* of the Roman writers, and the *Galatai* (Γάλαται), or *Keltai* (Κελται), of the Greeks, sometimes spoken of by the ancients as a general name for the Gauls, sometimes as the name of only a certain portion of the Gauls, the question arises, whence did the Gaels of Ireland, Scotland, and Wales derive their origin? A tradition exists that Ireland was colonised from Spain, where Celtic tribes certainly existed, and that the Highlands of Scotland were peopled from Ireland. This is not improbable; and Wales might have received the stock from the coast of France. This would account for the variations of the dialects. Diefenbach ('Sprachliche Documente zur Geschichte der Kelten') conjectures Galloway and Northumberland to have received the Celtic element from Ireland, and concludes that the Picts were the sea-rovers of Scandinavia. See also Zeuss's 'Grammatica Celtica e monument vetustistam Hibernicae ling. quam Britannicae Dialecti Cambricae, Cornicæ, Armoricae, nec non e Gallicae priscae reliquiis construxit,' Leipsic, 1853, as well as J. von Görres, 'Die drei Grund-Wurzeln des Celtischen Stammes in Gallien und ihre Einwanderung.' Munich, 1845–6.

There has been a world of controversy, also, about the origin and meaning of both *Gael* and *Celt* (anciently, it is to be remembered, pronounced *Kelt*); the confusion here again being increased by the difference of opinion as to whether these are different words or only different forms of the same word. The Greek *Galatai* and *Keltai*, the Latin *Galli*, the *Gael* of the Scotch and Irish, and the *Galles* of the French for Wales, seem all but variations of the same word. It is hardly necessary to enter into the meanings which the words *Gael* and *Celt* bear in the ancient Gaelic language, though they have caused much discussion.

It would occupy much more space than we can afford to enumerate even the more important works in which these various controverted points have been discussed in our own and other languages. We shall only mention 'The Highlanders of Scotland, their Origin, History, and Antiquities,' by W. F. Skene, 2 vols., 8vo, London, 1837, being an essay to which a prize had been awarded by the Highland Society of London. Mr. Skene's views and reasonings are of considerable ingenuity; but whatever may be thought of the part of it which relates to the origin of the Gael, the work is an important contribution to early Scottish history. The essay by the Rev. Archdeacon Williams, 'On One Source of the Non-Hellenic Portion of the Latin Language,' printed in vol. xiii. of the 'Transactions of the Royal Society of Edinburgh,' read in March, 1836, has much ingenious argument and learning in support of the theory we have already mentioned.

GAGE or GAUGE, any apparatus for measuring the state of a phenomenon. But the term is usually restricted to some particular instruments, such as the gage of the air-pump, which points out the degree of exhaustion in the receiver; the *steam-gage*, for measuring the pressure of steam; and the *gas-gage* for that of gas; also the *wind-gage* [ANEMOMETER], the *tide-gage*, &c., all of which are mentioned in connection with their several subjects. There are also various gages used in certain trades and manufactures, such as the *rod-iron gage*, the *nail-rod gage*, the *button maker's gage*; others are used in *watch-work*; there are also the *gun-maker's gage*, and gages for measuring wires and sheet metals. These generally consist of thick plates of steel of several sizes and forms, around and near the edges of which holes are drilled, with a notch leading from the edge into each hole. There is no system in the gages in common use, so that much confusion arises in attempting to reduce the measure to a common standard. Thus, the Birmingham gage for iron-wire, sheet-iron, and steel, differs from that used for sheet-brass, gold, silver, &c., and both these differ from the Lancashire gage for round steel wire. To render the confusion worse, gages nominally of the same value are made by different manufacturers without sufficiently agreeing as to the unity of measure.

To avoid these inconveniences, our best tool makers have long advocated the adoption of a uniform scale. Mr. Holtzapffel, in the appendix to the second volume of his 'Mechanical Manipulation,' proposes to employ only the decimal divisions of the inch, and those under their true appellations only. The division of the inch into a hundred parts would be sufficiently minute; and the measures 1, 2, 5, 10, 50, &c. hundreds would be sufficiently impressive on the mind. It does not follow that the entire hundred notches should be used; as in the greater thicknesses of wire and sheet metal the gradations from one size to another are not so minute as in those of the thinner kind. In the measurement of precious metal, where a hundredth of an inch might be too much, either there might be half-degrees or numbers, or a finer scale might be adopted below one-tenth of an inch. Holtzapffel enumerates the following advantages as likely to result from the use of such a decimal scale for denoting the thickness of wires, sheets, plates, &c.:—It would introduce a system which would be easily and *equally* known to all whom it might concern, and who would all interpret it in the same sense. It would facilitate the employing of verbal and written instructions, by lessening the chances of mistake or misinterpretation. It would render very easy the proportioning of various magnitudes so as to form a series. It would enable quantities to be written down more easily and accurately than at present. It would facilitate the comparison of one size with another; seeing that in vulgar fractions each has a *specific* relation to the unit, whereas in decimal fractions all have a *general* relation in common. It would bring all foreign measures within more easy reach of our knowledge. It would allow the exact weight in every superficial foot of sheet metals and other substances to be readily arrived at, by taking the specific gravity as the other element in the calculation. Lastly it would furnish constant multipliers for determining, from the specific gravities of substances, the exact thicknesses of plates or sheets of the same which shall precisely weigh one ounce or one pound, troy or avoirdupois. The graduation into hundredths being effected, the nomenclatures would follow easily; let a wire one-tenth of an inch in diameter, or a plate or sheet one-tenth of an inch thick, be called No. 10, and so on for other dimensions: there will then be swept away a large amount of confusion which now besets our factories and workshops.

Nearly related to this subject is Mr. Whitworth's exquisite contrivance for gaging or measuring minute quantities. In the Proceedings of the Institution of Mechanical Engineers, for 1859, an account of this remarkable machine is given; showing it to be the most accurate measuring apparatus yet devised. Newton's colures of thin plates, interpreted by formulæ of later introduction, show that a millionth of an inch is an appreciable quantity in relation to the breadth of waves of light; but Mr. Whitworth is the first who has felt justified in dealing with such extremely minute quantities as being measurable by strictly mechanical means. He can measure the relative lengths of two small pieces of steel, of which one exceeds the other by not more than *one millionth of an inch*. Nay, he feels confident of being able to test even one-half of this minute quantity. If we touch a piece of cold metal for an instant with the fingers, it expands by the increase of heat and the amount of this expansion we can measure. If the bar be a yard long, the touch even by a finger-nail is sufficient to produce an elongation which his machine can determine. The mechanism by which the astonishing result is produced mainly consists of exquisitely cut screws with graduated nuts or heads. At present, this is rather a scientific than a manufacturing agent; but Mr. Whitworth has succeeded in bringing into use new gages for wire-drawers and the manufacturers of sheet metal, in which the thousandth of an inch is an admitted and practicable element. Gages are now made, having decimal numbers on one side from No. 18 to No. 300, measuring from ·018 to ·300 of an inch. It will be for the manufacturers to decide how many thousandths of an inch there shall be in any particular sheet or wire; but this point once determined, Mr. Whitworth's gage will enable them to measure it. He observes, "I consider that for the shop the use of standard gages is better than any measuring machine, on account of the difficulty of using a sufficiently delicate instrument in regular shop-work, and the greater liability there would be to alteration in the standard both of diameter and length."

GALATIANS, ST. PAUL'S EPISTLE TO THE, one of the canonical books of the New Testament. Its authenticity has never been doubted: it was frequently cited by the apostolical and succeeding fathers (Lardner's 'Credibility of the Gosp. History,' vol. ii.), and was admitted by Marcion to a place among the apostolical writings. The date of this epistle is much disputed, some critics supposing it to have been written as early as A.D. 48, and others as late as 58. Two journeys of St. Paul to Galatia are mentioned in the Acts; one in A.D. 50 (Acts xvi. 6); and the other in 55 (Acts xviii. 23). It must have been written shortly after one of these visits, since St. Paul complains (i. 6) "that they were so *soon* removed from him that called them into the gospel of Christ unto another gospel." Michaelis, 'Introduction,' vol. iv., contends that it was written soon after the first visit, which took place probably about A.D. 49 or 50. But in chap. iv. 13, St. Paul himself says, "Ye know how through infirmity of the flesh I preached the gospel unto you *at the first* (τὸ πρότερον)," which proves that the apostle had visited them twice; and thus we may conclude that it was written after the second visit, or about A.D. 56 or 57, an opinion coincided in by the great majority of critical authorities. It is stated at the conclusion to have been written from Rome, but this is probably incorrect, though Michaelis and others support it.

It appears that shortly after St. Paul had left Galatia, some Judaising teachers had effected a great change in the churches of that country by teaching the Gentile converts that it was necessary for them to observe the ceremonial law, and submit to the rite of circumcision. They alleged that the other apostles taught this doctrine, and that St. Paul alone differed from them. They argued that the Galatians ought not to rely upon the authority of St. Paul, since he was not an apostle. These individuals were so successful that some of the Galatians appeared to have submitted to circumcision. To counteract these errors St. Paul wrote this epistle, in which he maintains that the authority of the other apostles could not be quoted as superior to his own, since he had received his apostleship from Christ himself, and had on this very subject "withstood Peter to the face, because he was to be blamed." (i. ii.) After thus vindicating his apostolical dignity, he argues in the remaining part of the epistle that the law had only been intended as a preparation for Christianity, as a "schoolmaster to bring men unto Christ, that they might be justified by faith," and that those who considered the observance of the Jewish law as necessary for salvation deprived themselves of the blessings of the Gospel. He concludes by exhorting them not to use the liberty which the Gospel gave them "for an occasion to the flesh, but by love to serve one another." On the undesigned coincidences with the 'Acts,' see Paley's 'Horæ Paulinæ.' The number of commentaries on this Epistle have been very numerous, in Latin, German, French, and English. One by Luther is still highly esteemed.

GALAXY. [MILKY WAY.]

GALENA. [LEAD, *Sulphide of.*]

GALILEE, in ecclesiastical architecture. In mediæval churches a portion of the western end of the church was frequently parted off from the rest and appropriated to strangers or those not numbered among the faithful. This was termed the Galilee, in allusion, as is supposed, to the scriptural "Galilee of the Gentiles." Sometimes in cathedrals it was an entrance porch, as at Ely and Lincoln; sometimes, as at Durham, a large chapel at the west end of the nave: see the plan of Durham Cathedral under CHURCH. It is said that this Galilee was built for the use of females, who were prohibited passing beyond the north porch in Durham Cathedral. In some parish churches a portion of the western end of the nave was marked off by a step or line of division, and called the Galilee.

GALIPEA. (*Materia Medica.*) The genuine Angostura or cusparia bark is obtained from a species of this genus, but whether from the *G. cusparia*, as stated by Humboldt, or from a distinct species, *G. officinalis*, as asserted by Dr. Hancock, is not determined. Angostura bark is obtained both from the stem and branches; the specimens from the stem are flat, from 2 to 3 lines thick, while those from the branches are often quilled, and from ½ to 1 line thick. The pieces are sometimes from 6 to 15 inches, but more frequently only from 2 to 6 inches long, and from ½ to 2 inches broad. Some specimens have the surface covered with a thick, fungus-like, whitish-yellow or clay-coloured crust, which may be more or less easily scraped off, and beneath which is a yellowish-red smooth bark, often exhibiting small cracks. Other specimens have this covering much thinner and closely adhering to the bark. The internal surface is generally smooth, of a tawny or reddish-yellow colour.

The bark is easily broken, and the recent fracture is of a brownish-red colour, smooth, with a resiny shining surface. The shining appearance is best seen when a transverse section is made with a sharp knife. The smell is disagreeable: the taste pleasantly bitter, warm, aromatic, and causing a flow of saliva. The powder has the colour of rhubarb. The infusion is of an orange-yellow colour; the decoction a clear light brown.

Brandes thought that he had discovered an alkaloid, which he proposed to call Angosturin, but it has not been detected by subsequent chemists. This bark contains neither gallic acid nor tannin. According to the analysis of Fischer it consists of—

Volatile oil (of an acrid nature)	0·3
Bitter hard resin	1·7
Balsamic soft resin	1·9
Elastic resin	0·2
Bitter matter (Angosturin bitter)	3·7
Gum	5·7
Woody fibre	89·1
	102·6

So minute an account of this substance would not be necessary, were not the true Angostura bark liable to be confounded with the false, which possesses such poisonous properties that very fatal consequences have resulted from the substitution of the one for the other. It has been ascertained beyond any doubt, that the false Angostura bark which comes from the East Indies, is the bark of the Strychnos nux vomica. But even in Calcutta this false bark is confounded with *rohuna*, the harmless bark of *Soymida febrifuga*. [SOYMIDA.]

False Angostura bark was first observed in 1804 by Dr. Rambuch, of Hamburg, by poisonous effects following the use of a decoction of the bark; and similar consequences having been observed at Vienna, the Austrian government ordered all the Angostura bark in the empire, genuine as well as false, to be burnt, and interdicted its future importation. The Russian and Würtemburg authorities made known the danger, and published the marks of distinction, which are sufficiently characterised, and to prevent accidents, may be here enumerated.

GENUINE.	SPURIOUS.
Pieces 2 to 4 inches long; from ½ to 2 inches broad; from ½ to ¾ of a line thick.	Pieces of greater breadth than length; thickness never less than a line, often two lines.
Epidermis having on it a number of different lichens (often as many as 40 species), and a yellow membranous crust.	Epidermis generally clear (but sometimes undergoing a peculiar transformation), and seldom having any, or not more than two lichens (*Opegrapha Pelleticri*, and *Pyrenula nitida*). A species of chiodecton has been supposed to be found on it, but this appearance arises from an alteration of the epidermis.
The incrustation spongy and insipid, and not changing colour by the action of nitric acid.	The crust has the general properties of the bark, and assumes a deep green by the action of nitric acid. It contains a resinous colouring principle, Strychnochromin.
Crust easily removed by the nail.	Crust not easily removed.
Inner surface yellow, and separable into layers.	Inner surface brown, or even black, not separable into layers.
Texture not close, weight light, easily broken, fracture even, shining, and resinous. Cuts transversely without difficulty.	Texture compact, heavy, not easily broken, fracture even, but not shining or resinous, exhibiting two layers. Very difficult to cut.
Placed in water it soon imbibes it, and becomes soft.	Scarcely softens in water.
Smell strong and disagreeable.	No smell.
Taste an aromatic and enduring bitter, but not at all disgustingly bitter.	Taste in the highest degree disgustingly bitter; very durable, and not at all aromatic or astringent.

Spurious Angostura bark, in the dose of eight grains, killed a dog in two hours; ten grains killed a young dog in a few minutes. A very small glassful of an infusion endangered the life of an adult, while a dose of the decoction destroyed a child with acute suffering. Ether and laudanum seem to act as antidotes. Oil of turpentine may be used, but vinegar must be avoided. The dread of similar casualties from the employment of the spurious instead of the genuine Angostura bark, has prevented the use of the latter to that extent which it merits. In the treatment of the bilious diarrhœa, frequent in damp autumns in this country, after proper evacuants, it is of the most decided utility. In common English cholera likewise, and slighter cases of Asiatic cholera, it is the most beneficial agent which can be resorted to. It is best given in the form of infusion, and may either be administered alone, or with the addition of dilute nitric acid and tincture of opium, which last may be discontinued after a few doses. (Abercrombie, 'On Diseases of the Stomach,' &c.)

Re-agents produce the following effects on a cold infusion of each :—

Colour of Infusion of Genuine, Orange Yellow. *Colour of Infusion of Spurious, Light Yellow.*

Cold Infusion.	Tincture of Galls.	Bi-chloride of Mercury.	Sulphuric Acid.	Protosulphate of Iron.	Perchloride of Iron.	Carbonate of Potass.
Genuine Angostura.	Yellowish precipitate.	Copious precipitate.	Very turbid.	Whitish-gray precipitate.	Yellowish brown precipitate.	Dark red colouring, with slight precipitate.
Spurious Angostura.	White precipitate.	Renders turbid only.	No action.	Green colour, slightly turbid.	Yellowish green colour.	Greenish colouring, with dirty yellow precipitate.

GALLSTONE. [Cholesterin.]

GALL-STONES. [Calculus.]

GALLAMIC ACID. [Tannic Acid.]

GALLATES. [Tannic Acid.]

GALLEON (*galoion* in French, *galen* in Spanish) was the name given to very large ships, with three or four decks, of which many were employed in the Spanish Armada in 1588. Subsequently the name became restricted to the large vessels which the court of Spain used to send at fixed periods to the coasts of Mexico and Peru, to receive on board the gold and silver bullion extracted from the mines, and bring it to Spain. Commodore Anson intercepted, and captured after a short engagement, one of these galleons on its way from Acapulco to Manilla.

GALLERY of Mine is the passage leading from the shaft or entrance of the mine to the place where the powder is deposited. [Mine, Military.]

GALLERYTHRONIC ACID. [Tannic Acid.]

GALLEY (*galère* in French, *galèra* in Italian and Spanish), a large-sized vessel propelled by oars and sails, which was much in use in the Mediterranean until the end of the 18th century. It carried two masts with lateen sails, was long and narrow, and drew but little water; it was therefore calculated for coast navigation, and for making the shore in shallow water; and by means of its oars it had a great advantage, in the dead calms so frequent in the Mediterranean, over sailing vessels, an advantage in which it has been effectually superseded by the introduction of the steam-boat. Even long before that invention the use of galleys as a naval force had been given up by France, their construction rendering them unfit for long navigation, and for encountering the waves of the ocean. The Knights of Malta, Naples, the Pope, and other Italian states, were the last to continue the use of galleys for the purpose of coping with the Barbary privateers, whose vessels, although of a similar description, were generally smaller and unable to resist the large and well-disciplined galleys of the Christian powers. The largest galleys were 166 feet long and about 32 wide, with 52 oars. The rowers, who were generally convicts or Turkish prisoners, with chains to their feet, sat on benches on the deck. The ship carried a 24-pounder and two 8-pounders. (See a description and plate of a large-sized galley in the 'Dictionnaire de Marine,' article *Galère* in the 'Encyclopédie Méthodique.')

The galleys appear to have been an imitation of the ancient triremes, and they retained the ancient names for several parts of the rigging, such as "antenna," &c. The felucca is a kind of small galley. [Felucca.] The Venetians had a sort of large galley, with a very lofty poop, called "Galeazza."

GALLIARD (*Gagliarda*, Ital.), a lively dance in three-crotchet time, which had its origin in Rome, but has fallen into disuse.

GALLIC ACID. ($3HO,C_{14}H_3O_7+2Aq.$) The well-known astringent property of various parts of plants is due to the presence of tannic or gallic acids. Gallic acid occurs in far less abundance than tannic acid. It may be extracted directly, by precipitating tannic acid from an aqueous infusion of a bark, root, &c., by means of solution of gelatine, and then evaporating the filtered liquid, which contains the gallic acid, to dryness. The residue, digested in alcohol, treated with animal charcoal and the solution allowed to evaporate spontaneously, yields the gallic acid in a crystalline state.

Gallic acid is, however, usually prepared by a kind of fermentation from the tannic acid in nut-galls. [Galls, in Nat. Hist. Div.] Powdered galls, well moistened with water, are exposed in a warm place to the action of the air for two or three months. Mould rapidly forms on the surface of the mass, and must be occasionally removed; oxygen is absorbed and carbonic acid evolved. On subsequently boiling the whole in a considerable quantity of water, gallic acid is dissolved out, and is deposited in crystals on the cooling of the liquor.

When obtained quite pure, by recrystallisation from alcohol, and the usual treatment with animal charcoal, gallic acid is obtained in long, silky, nearly colourless needles or prisms of astringent taste, but no odour. They are soluble in one hundred times their weight of cold water, but in three parts of boiling water. Alcohol dissolves them readily, ether only sparingly. A heat of from 410° to 420° Fahr. causes the decomposition of gallic acid into *pyrogallic acid* which sublimes in brilliant white crystals, and carbonic acid, which is evolved as gas. The sudden application of too high a temperature (above 480°) to gallic acid causes the evolution of water as well as carbonic acid and *metagallic acid* or *gallulmic acid* remains. Ebullition with strong solution of potash converts gallic acid into *tannomelanic acid.* Gently heating with sulphuric acid converts it into *rufigallic* acid, while nitric acid rapidly oxidises gallic acid to oxalic acid.

Gallates are formed by the union of gallic acid with bases. In this way three classes of salts result :—

Monometallic salts . . .	$MO, 2HO, C_{14}H_3O_7$
Bimetallic salts	$2MO, HO, C_{14}H_3O_7$
Trimetallic salts . . .	$3MO, C_{14}H_3O_7$

In the solid state the gallates are tolerably stable, in solution they rapidly absorb oxygen if exposed to the air and are decomposed. The characteristic reaction for the detection of gallic acid is the production of a deep bluish-black solution on the addition of a mixture of proto- and per-salts of iron.

GALLIOT, a strong-built flat-bottomed vessel of a peculiar construction, used as a bomb-ship to fire against forts or batteries on the coast. The largest are of the burden of 400 or 500 tons, and above 100 feet in length. See account and plate of the same in the 'Dictionnaire de Marine,' in the 'Encyclopédie Méthodique,' art. "Galiotte." Galliot is also a kind of small galley or large felucca, used chiefly in the Mediterranean, especially by the Barbary corsairs. [Galley.] The Dutch, Swedes, and other northern nations have a sort of merchant-ship which they call Galliot, heavy and clumsily built, but strong of timber, rounded both fore and aft, and of the burden of from 200 to 300 tons.

GALLITANNIC ACID. [Tannic Acid.]

GALLON, an old English measure of capacity. The Latin of the middle ages is *galo, galona, jalo, lagena,* &c. Dr. Bernard thinks the latter is the original. Ducange cites an old assize of David of Scotland, in which it is said the *lagena* should contain 12 lbs. of water, namely, 4 of sea water, 4 of still water, and 4 of running water. But that various gallons were used is evident from statutes of Henry III. and later kings, in which it is enacted that ale, wine, and corn shall be measured by the same gallon, containing eight troy pounds of dry wheat from the middle of the ear. These statutes produced no effect, and distinct gallons for wine, ale, and beer, and corn and dry goods, continued in use until the Act of 5 Geo. IV., c. 74, which came into operation May 1, 1825.

By statutes of 1689 and 1697, the wine gallon was declared to contain 231 cubic inches. But in 1688, by an experiment, at which Flamsteed, Halley, and others (among whom was Ward, author of the 'Young Mathematicians' Guide,' who relates the circumstance) were present, it was very distinctly proved that the sealed gallon at Guildhall (which was the *usual* standard) contained only 224 cubic inches. "However," says Ward, "for several reasons it was at that time thought convenient to continue the former supposed content of 231 cubic inches." The fact was, that the Guildhall gallon was an incorrect copy of the old Exchequer standard, placed in a more accessible locality. Previously to this, Dr. Bernard had stated his full conviction, from the measurements of predecessors whom he cites, that the said gallon contained 223·549 cubic inches; the agreement of these two experiments leaves no doubt as to their accuracy. By the Act of the 5th of Queen Anne, the wine gallon of 231 inches was made the standard; and a gallon was accordingly constructed for the Exchequer, which the committee of the House of Commons, in 1758, found to contain 231$\frac{8}{10}$ cubic inches. The account of the experiment in 1688 was preserved, and is cited by the committee.

The ale gallon was measured in 1700 or thereabouts, and found to contain 282 cubic inches. Ward imagines that this gallon was meant to bear the same relation to a pound avoirdupois which the wine gallon did to a pound troy; and 231 is to 282, very nearly as 5760 to 7000, the latter being the proportions of the two pounds. But if the wine gallon were only 224 cubic inches, then the ale gallon should have been 272¼; or, as we shall see, the corn gallon much more nearly coincides with the hypothesis.

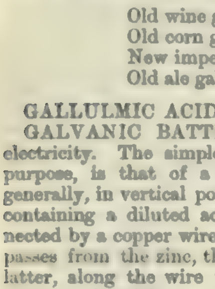
The corn gallon was thought, in the middle of the last century, to contain exactly 272¼ cubic inches. Dr. Bernard, on the same authorities, states it to have been determined at 266 cubic inches; and the statute of 1697, which declares that a round corn-bushel must be 8 inches deep and 18½ inches wide, had in fact fixed the gallon at 268$\frac{8}{10}$ cubic inches.

The imperial gallon, as settled by the Act of Geo. IV., is to contain 10 lbs. avoirdupois of distilled water, of which it is declared that 252·458 grains fill a cubic inch: consequently, the imperial gallon contains 277·274 cubic inches; being very nearly a mean between the old ale and (previously to 1697) corn gallon. According to the parliamentary standards, then, we have

Old wine gallon, 231 cubic inches.
Old corn gallon, 268·6 cubic inches.
New imperial gallon, 277·274 cubic inches.
Old ale gallon, 282 cubic inches.

GALLULMIC ACID. [GALLIC ACID.]

GALVANIC BATTERY. An apparatus for generating *current* electricity. The simplest combination which can be formed for this purpose, is that of a plate of zinc and a plate of copper placed, generally, in vertical positions and parallel to one another in a vessel containing a diluted acid, the upper edges of the metals being connected by a copper wire. In this state a current of positive electricity passes from the zinc, through the acid, to the copper, and from the latter, along the wire to the zinc: at the same time a current of negative electricity passes from the zinc, along the wire, to the copper, and from thence, through the acid, to the zinc. It is evident that the quantity of fluid furnished by a combination of this kind will be proportional to the superficies on which the acid can act; and an apparatus designated a *battery*, which may be said to consist of two plates only, one of zinc and the other of copper, was executed many years ago for the London Institution. Each plate was 50 feet long and 2 feet wide, and the two were coiled together upon a cylinder of wood, so as to leave everywhere an interval between the two metals: in that interval rope-bands of horse-hair were passed round with the coils so as to keep the metals asunder. The dilute acid was contained in a cylindrical vessel; and when the battery had to be used, the coils of metal were lowered by machinery into the vessel.



One of the earliest forms of apparatus was the *pile* of Volta, in which were combined together a considerable number of small plates of zinc and copper, alternately, with the acid between them. Under GALVANISM are explanations of the electrical action that takes place, and we here merely describe the construction of the pile. A circular plate of zinc, *z*, usually about 1½ inch diameter and $\frac{1}{10}$ inch thick, is laid upon and generally soldered to a thin plate of copper *c*, of equal diameter; and any convenient number of these are placed above one another, with the copper side undermost in all: between every two compound plates is a circular piece of paper *p*, or cloth moistened with diluted sulphuric acid; and the whole column or pile is made to preserve a vertical position by being formed within three pillars of glass or baked wood, which are connected together by having their extremities inserted in boards, of which the lower one serves as a base for the column. The paper or cloth should be rather less in diameter than the plates of metal; and no moisture should be allowed to escape over the edges of the plates.

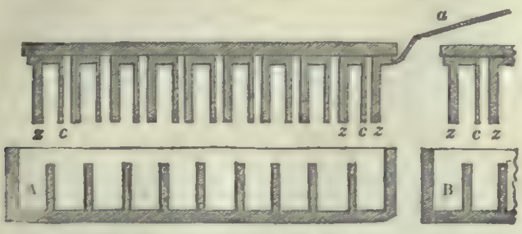
In this state the lowest plate of zinc attracts the positive electricity from the copper below it, and this continually receives a supply from the earth through the table, or the base of the pile; the quantity thus attracted is conveyed to the copper plate immediately above, through the moistened cloth, the latter serving as a conductor: again, the zinc in the second plate attracts electricity from the copper below it, and, at the same time, receives that which is transmitted to the latter from the zinc in the lowest plate. Thus the quantity of positive electricity in the zinc of the second plate becomes nearly twice as great as that which is in the lowest plate; and the process continuing, the quantity in the zinc of each plate above may be conceived to be such a multiple of that which is in the lowest plate as is expressed by the number of the compound plate from the bottom of the pile. There is consequently obtained a current of positive electricity passing upwards from the zinc, through the acid, to the copper; and if a copper wire be made to pass from the top of the uppermost zinc plate to the copper in the lowest plate, the same current will return downwards, so that a circulation of the fluid will continue till the energy of the pile is exhausted. At the same time there is a current of negative electricity passing down the pile from the copper, through the acid, to the zinc, and returning upwards along the wire.

If a second pile be formed, the plates in it may be placed in a reverse order, the copper side above and the zinc side below: if a third pile be formed, the order may be the same as in the first pile; if a fourth, the same as in the second; and so on: then, in uniting them together, a metal wire passes from the copper at the bottom of the first pile to the zinc at the bottom of the second; another wire passes from the copper at the top of the second to the zinc at the top of the third, and so on.

When a wire connects the opposite ends of one pile, or of a system of piles, the circuit is said to be *complete*: it is said to be *broken* if there are two separate wires, one proceeding from the copper at bottom, and the other from the zinc at the top. If an animal body were in connection with the farther extremities of the wires it would complete the circuit, and experience shocks.

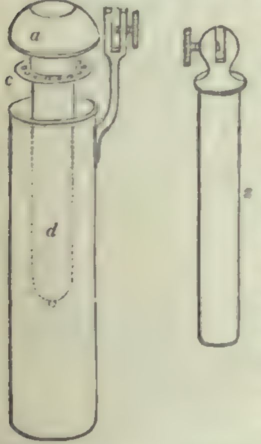
The opposite extremities of the pile, or of the wires which are in contact with them, are called the *poles* of the battery. As the current of positive electricity seems to issue from the zinc at the top of the pile, that extremity is called the *positive pole* of the battery; at the same time the negative electricity seems to issue from the copper at the bottom, and therefore the terminating copper plate is called the *negative pole*. These designations are reversed when a single pair of plates separated by an acid is mentioned. In that case, since the positive electricity passes from the zinc plate, through the acid, to the copper-plate, and the wire passes through the air from the edge of the copper to that of the zinc plate; it is evident that the positive electricity will flow from the copper, and therefore the copper is the positive pole of the combination; the negative electricity flowing at the same time along the wire, from the zinc, the latter is the negative pole. The terms *positive* and *negative* poles, as applied to the extremities of the battery, have been objected to on the ground that before connecting the two terminal wires no electricity is evolved, and when the connection is formed the electricity moves in a circuit, no portion of which is apparently more positive or more negative than another portion. Hence Faraday proposed, instead of pole, the word *electrode*, which signifies a *way*: for the negative pole *cathode*, signifying the *descending way* or *downwards*; and for the positive pole *anode*, which signifies *ascending way* or *upwards*. In forming these terms he supposed the battery to be placed on the ground with its copper or + end to the east, and the wire connecting the ends of the battery to be bent into an arc, similar to the course of the sun; in such case the electric current would flow up from the east end of the battery, and descend into it at the west end. The fluid decomposed by a current passing through it was termed an *electrolite*: the elements liberated by the decomposition were termed *ions*; those which appeared at the cathode were named *cations*, and those set free at the anode *anions*; thus in the decomposition of sulphate of copper the metal is the cation, and the acid the anion. Daniell employed the word *platinode* for the negative, and *zincode* for the positive pole; while Graham introduced the terms *zincous* and *chlorous* poles, to represent the + and −. Much of this nomenclature appears to us to be as uncouth as it is unnecessary: it was introduced at a time when the introduction of the constant battery by Daniell, and the splendid discoveries by Faraday, had somewhat unsettled the scientific mind on the subject of voltaic electricity. The new terms, with a few exceptions, have scarcely obtained a footing; which is not surprising, seeing that the old expressions *positive* and *negative poles*, and *electro-positive*, and *electro-negative bodies*, are far more simple and quite as accurate as the terms by which it is proposed to supersede them.

As the arrangement of the pile was inconvenient for experimental purposes, and, moreover, did not give much power, and the power that it did give was soon exhausted, an arrangement was introduced called the *trough battery*, of which there were many forms. The first consisted of the pile, with the plates on edge, cemented into grooves made in three sides of a wooden trough, spaces being left between every two compound plates for pouring in dilute acid, which took the place of the paper or cloth. In another form, the trough was made of glazed earthenware, by nine or more parallel partitions of the same material, which permitted no communication between one cell and another. As many pairs of plates, zinc and copper, of equal superficies, as there were partitions, were provided; the two plates of each pair were soldered or fastened together at their upper extremities, so that they might be parallel to one another, and all were united together by a rod of wood, so that they could at once be placed into or removed from the cells. The bridges or connections between the zinc and copper plates stood directly over the partitions, so that there was a copper and a zinc plate in each separate cell, except at one extremity of each trough, in which, till two troughs were connected together, the cell had only a zinc plate. When one trough was to be connected with another, in order to increase the battery, a slip of copper, as at *a*, soldered at the top of a zinc plate, was bent and made to enter the cell B, containing only a zinc plate at one end of the preceding trough. In order to form the complete circuit, one extremity of a wire was made to enter the cell A, for example, which was the positive end, and the other extremity was brought to the opposite end of the trough, or series of troughs, where it was placed in contact with the copper slip, as *a*: the positive current then flowed along the wire from the extremity first mentioned to the other.



The above form was contrived by Mr. Children; but Dr. Wollaston proposed, as an improvement upon it, to have in each cell a zinc plate between two plates of copper; for thus both surfaces of each zinc plate would become efficient in producing the electric current, and the power of the battery would be increased by one half. The battery at the Royal Institution was of Mr. Children's kind; it contained 2000 pairs of plates, each 8 inches long and 4 inches deep, and with it Sir Humphry Davy made his principal discoveries.

The battery invented by Professor Daniell consists of any number of cylindrical vessels of copper, open at the top, about 16 inches high and 3 inches in diameter, and containing a saturated solution of sulphate of copper; the exterior surface of each may be painted, but the interior, which alone is efficient in producing electricity, is made bright. On the top of the cylinder is placed a hemisphere *a* of wood, through which, in the direction of the axis of the cylinder, is a perforation above an inch in diameter; and to its base is attached a short tube *b* of copper, less in diameter than the cylinder, and carrying near its upper extremity an annular plate *c* of copper, in which are pierced several small holes. When the wooden cover is placed on the cylinder its base rests on the top of the latter; and the part of the cylinder between the short tube and the annular plate is filled with crystals or pieces of sulphate of copper, which, gradually dissolving, preserve the strength of the solution in the lower part of the cylinder.



To the interior of the short tube was affixed, in the original arrangement, one end of a piece of ox gullet *d*, about the same length as the copper cylinder, and having its lower extremity tied so that the whole formed a membranous bag; this is to contain diluted sulphuric acid (eight parts water to one of acid). A rod of zinc *z*, about the same length as the cylinder, an inch in diameter, and terminating at the upper extremity with a brass ball, is passed through the perforation in the wood, down the interior of the membrane, so that its shoulder rests on the top of the wood; the surface of the zinc being previously covered with an amalgam of mercury. Instead of a membrane, a bag of paper or canvas, or a vessel of porous earthenware, may be more conveniently used.

If now, a connection, by means of a wire or metallic rod, were made between the ball at the top of the zinc rod and the top of a stem *e* which rises from one side of the copper cylinder, the zinc will be corroded by the sulphuric acid, and the electric fluid will pass to the copper through the acid, the membrane, and the solution in the cylinder. [GALVANISM.]

The battery invented by Mr. Grove consists of several porous vessels containing strong nitric acid, and, in each, a rod or plate of platinum; each of these vessels is placed between two plates of zinc within a trough in which is diluted sulphuric or muriatic acid. The rod of platinum holds the place of the plate of copper in Children's battery, and constitutes the negative pole of each combination; the zinc plate being the positive pole. By mixing sulphuric acid with the nitric acid in the porous cells, a more uniform current is obtained. This battery is expensive, and must be placed under a chimney or a hood to carry off the nitrous fumes. For the sake of economy Bunsen uses, instead of the platinum, cylinders of carbon prepared by heating a mixture of powdered coke and caking coal, or powdered coke moistened with a strong solution of sugar. The carbon answers very well while fresh, but it soon deteriorates by absorbing the nitric acid. Poggendorf uses sheet or cast iron, which is not acted on by strong nitric acid. In Smee's battery the negative or conducting plate is of silver, on which finely divided platinum has been deposited, this roughness of surface facilitating the escape of the hydrogen; each side of the silver plate is exposed to a plate of amalgamated zinc of the same size, which acts as the positive plate, and is excited by dilute sulphuric acid.

Grove's *gas battery* possesses a theoretical, rather than a practical interest. It is stated, under GALVANISM, that the amount of force set in motion in a voltaic arrangement depends on the difference between the affinity of the two metals for the active principle, or radicle of the acid. The liquid which excites the chemical action is decomposed, its elements are separated, and they either combine with the metallic plate, or accumulate on its surface. By these means the voltaic action is opposed and enfeebled, in consequence of the tendency of the component parts of the fluid to re-unite; for example, when dilute sulphuric acid is used, it is important to get rid of the hydrogen which adheres to the platinum, and produces a counter-current, which may be made evident by connecting a platinum plate, opposed to a zinc plate with a galvanometer wire, when, on attaching to the other end of the galvanometer wire another platinum plate, free from hydrogen bubbles, and plunging both into dilute acid, the needle will be powerfully deflected. In the gas battery a plate covered with oxygen, is opposed to a plate covered with hydrogen. A cell of this battery consists of two tubes; through the upper end of each is soldered a platinum wire attached to a platinum plate extending to the bottom of the tube. The hydrogen tube has twice the capacity of the oxygen, and the tubes are supported in a vessel containing dilute sulphuric acid. At the beginning of the experiment the tubes are filled with the dilute acid, and are charged with gas, by being connected with a voltaic battery. When the tubes are in this way charged, they are separated from the battery, and the mercury cups at the top of the tubes being connected with a galvanometer there is a strong deflection of the needle, and by connecting 8 or 10 cells in such a way that the oxygen of one cell may be connected with the hydrogen of the next cell, sparks between charcoal points and various chemical decompositions may be obtained. The gases gradually diminish in bulk, but the current is maintained so long as they remain uncombined.

For the formation of a voltaic circuit, it is usually stated that two dissimilar metals, and a fluid acting upon one of them, are required. We have seen in the case of the gas battery a variation from this rule, which may be still farther departed from in various ways. For example:—if a single metal be plunged one end into a liquid capable of acting on it, while the other end is dipped into a different liquid communicating freely with the first liquid, but having little or no action on the metal, a current will be established. If, for example, we place in the bend of a U tube a piece of tow, and in one limb pour in a solution of chloride of copper, and in the other limb one of common salt, and connect the two open ends of the tube by means of a strip of copper dipping therein, crystals of copper will be formed upon the end of the strip immersed in the metallic solution, while the end of the strip immersed in the salt and water will be corroded, and chloride of copper be formed. By using various liquids in the two limbs, Becquerel has obtained many of the metals in beautiful crystalline forms. It has also been shown that similar actions are going on within the earth's crust; for by connecting, by means of wires attached to a galvanometer, the surfaces of two contiguous lodes of ore, the existence of feeble but continuous currents was detected.

The battery used at first by Professor Wheatstone for his electrical telegraph was formed nearly on the same principle as that of Mr. Daniell. A small outer vessel contained a solution of sulphate of copper, together with the plate of copper which formed the negative pole; within this, a small porous cell contained diluted sulphuric acid, and at the bottom was an amalgam of zinc and mercury, which constituted the positive pole. Various other forms of battery, and also an electro-magnetic apparatus, have been employed for working the telegraph. [TELEGRAPH.]

A notice of galvanic apparatus would not be complete without referring to Deluc's *dry pile*, which consists of circular disks of paper, one surface of which is coated with leaf gold or silver, and the other surface with zinc foil. Some thousands of these disks are arranged in a glass tube, with all the zinc surfaces in one direction, and the silvered or gilt surfaces in the other direction. If these disks be pressed together, and a wire attached to each end, the leaves of the gold-leaf electroscope may be made to diverge by touching the cap of the instrument with one end of the pile, and connecting the other end with the earth. If the two ends of the pile be made to terminate in metal disks placed about an inch or so from each other, and be well insulated, an insulated slip of gold-leaf suspended midway between them will oscillate backwards and forwards for months, and even years. A dry pile consisting of 20,000 disks gave sparks, and charged a Leyden battery so as to produce shocks. The term dry pile is, however, a misnomer, since the action depends on the moisture contained in paper when exposed to the air: if the paper be artificially dried the pile ceases to act. Zamboni substituted finely-powered peroxide of manganese for the gold or silver leaf, with good effect. The pile terminated in metal plates, which compressed the paper disks by means of ligatures of silk, and the pile was insulated by giving it a coating of sulphur.

In all voltaic actions power is transferred by means of a polar influence propagated through the solid as well as the liquid particles of the circuit. As a consequence of polarisation we get electric tension, the effects of which may be shown by a numerous series of alternations of zinc and copper (Mr. Gassiot's battery consisted of 3520 pairs), each exposing but a very small surface, and excited with distilled water only. Such an arrangement is called a *water battery*, and when well insulated its effects are remarkable. With 1000 couples divergence of the gold leaves of an electroscope was produced, a charge was given to a Leyden battery, which, though weak, could be discharged and renewed any number of times in rapid succession. In Mr. Gassiot's arrangement, when the wires terminated in brass disks, placed very near together, a rapid succession of sparks was kept up, on one occasion, for five weeks; the galvanometer was permanently deflected, and paper moistened with iodide of potassium gave indications of decomposition, although the chemical effects of the water battery are but feeble.

Under Electro-Dynamics will be found some formulæ for estimating the force and resistance of galvanic currents; and we gave a brief statement of Ohm's method of representing the mutual actions of the electro-motive forces, and the resistances of any circuit in the form of a fraction. Now as the power of any combination, simple or compound, is directly proportioned to the electro-motive force, or chemical energy between the active metal, and one of the elements of the liquid on which it acts, and inversely proportioned to the resistances to be overcome, the numerator of the fraction will be represented by E, the electro-motive force, and the denominator by $R+r$, R representing the resistance in the cell or the battery (chiefly due to the affinity between the elements of the liquid for each other), and r all resistances exterior to the cell and the battery, such as that of the connecting wire: then the expression $\frac{E}{R+r}=A$ would represent the effect of any combination where A indicates the amount of force in circulation, whether measured by its heating or by its magnetic effects. If the connecting wire be very thick, so as to offer little or no resistance to the current, r goes out, and the fraction becomes $\frac{E}{R}=A$. Now, suppose that when a pair of zinc and platinum plates, 6 inches in length and 1 inch in breadth, and 1 inch apart, is immersed in dilute acid, $E=1$ and $R=1$ then $\frac{E}{R}=\frac{1}{1}=1$. If a pair of plates, 6 inches broad and 6 inches long, be immersed in the same acid, since the resistance is inversely as the surface of the plates immersed, the fraction becomes $\frac{E}{\frac{R}{6}}$ or $\frac{1}{\frac{1}{6}}=6$, or the power is increased six-fold, as compared with the former. If each of the plates be cut into six similar slips, and these be arranged in pairs, all the platinum plates connected by the same wire and opposed to all the zinc plates similarly connected, the same fraction still represents the result, since the relative size and distance of the plates remain unchanged; but if the plates be made to alternate, the zinc of one pair connected by a wire to the platinum of the next pair, so as to produce a compound circuit, the fraction becomes $\frac{6E}{6R}=\frac{6}{6}=1$, the electro-motive force is increased six-fold, but the resistance is also increased in the same proportion. The force, which in this case circulates through the connecting wire, is not greater than if a single cell, containing a pair of plates 1 inch broad and 6 inches long, had been employed. If, however, the connecting wires were several miles in length, as is the case in the electric telegraph, r becomes important. We will suppose the resistance to be twenty-fold greater than that of the liquid in each cell: then, in the case of the simple circuit, the fraction becomes $\frac{E}{\frac{R}{6}+r}=\frac{1}{\frac{1}{6}+20}=0{\cdot}049$; and in the case of the compound circuit, $\frac{6E}{6R+r}=\frac{6}{6+20}=0{\cdot}23$; so that although in both cases the resistance greatly diminishes the amount of circulating force, the power in the compound circuit is five times as great as that produced by the simple circuit, so that wherever there is a great external resistance, a compound battery is very much to be preferred to the simple circuit. For, let n = the number of plates in a compound circuit, E the electro-motive force, D the distance between the plates, S the area of the plates, l the length of the conducting wire, s the area of a section of the wire, then the action of a compound battery with its extremities connected by a thick metallic wire, is expressed by the fraction $\frac{nE}{\frac{nD}{S}+\frac{l}{s}}=A$. In Professor Miller's 'Elements of Chemistry,' part i., the reader will find some further instructive applications of Ohm's theory. The chemical decompositions produced by the galvanic battery are stated under Electro-Chemistry; and the brilliant light furnished by the voltaic arc is noticed under Electric Light. See also Electrical Egg.

GALVANISM. This department of electricity takes its name from Galvani; but its infant progress was due in a much greater degree to his contemporary Volta, by whom piles were first constructed for increasing the intensity of the electricity produced by a single pair of plates. The production of electricity in this case arises from the action of the acid in the cell between two plates of dissimilar metals, that which is the more oxidable giving out positive electricity, as explained under Electro-Dynamics. The forms in which the piles have been constructed are various, and the number of plates is adapted either to the quantity or intensity of electricity which may be desired. When quantity with a feeble tension is requisite, a single pair of plates, such as zinc and copper, with extensive surfaces, separated by very dilute acid, will answer; but with a system of pairs of plates, where the copper of the first pair *conducts* its electricity to the zinc of the second, and so on, the quantity and intensity are increased with the number of the plates. In some constructions, as Ritter's dry piles, the plates are simply laid on each other, those of each pair being separated by moistened paper; in others the plates lie parallel in a trough of baked wood, by which means the cells are easily filled and emptied. In the *Couronne de Tasses* of Volta the plates are placed circularly or in a bowl shape; while in Hare's *Calorimotor* there is merely one zinc plate and one copper twisted into a great number of coils, which form increases the intensity, as may be seen from the article Electro-Dynamics. All these forms have however been superseded by the constant battery, as noticed under Galvanic Battery.

The electricity thus produced is of the same nature as that given by the common machine; the only difference being that the mode of producing galvanism is continuous, that is, when in any way discharged it is immediately reproduced by the oxidation of the zinc; and hence many galvanic phenomena have been successfully imitated by a series of sparks of ordinary electricity. When the positive and negative wires are made strictly to communicate by metallic conductors, the combination of the opposite electricities causes all phenomena analogous to those produced by the ordinary machine to cease, but gives birth to the electro-dynamic and electro-magnetic phenomena. [Electro-Magnetism.] But when the wires from the opposite poles of the battery are only brought sufficiently near that the current may pass through an interposed substance, or when the circuit is completed by imperfect conductors, the physical changes which the interposed substances undergo constitute the phenomena of galvanism. It may be observed that the relative conductibility of substances for Voltaic is nearly the same as for common electricity, but the alterations produced by the former in the temperature and internal nature of the substances through which the current is admitted interfere in some degree with that order of conductibility.

The deflagration of metals is effected by beating them into thin leaves, which are then interposed between the extremities of the positive and negative wires of the battery, brought within a quarter of an inch of each other: they will then burn with a beautiful light, but which is of different colours in different metals. Thus—zinc gives a white light with a reddish border; copper, a bluish white light, and throws out red sparks; lead, a purple light; gold leaf, a beautiful white light tinged with blue.

But if the interposed substances, instead of being laminæ, be of small irregular forms, or wire-shaped, their temperature rises rapidly as the electric current permeates them. Steel burns, iron wire dissolves in globules, while charcoal produces a light of such dazzling brilliancy as to fatigue the eye, a property which has been happily seized by employing it in the solar microscope [Electric Light]; yet this heat and light are independent of the ambient medium, no oxygen is consumed, and the attenuation of the air rather adds to than diminishes the light. As for the apparent diminution of this intense light when the charcoal is immersed in water, it is attributable to the imperfect conductibility of the latter medium; a thermometer placed in water, in which the wires are immersed, will rise even to the boiling point. Mr. Children has given a list of the order of facility in which substances thus acquire a red heat, and has succeeded in fusing the oxides of molybdenum, tungsten, uranium, &c., but found ruby, sapphire, silex, quartz, &c., more intractable. It is obvious that, in the estimation of such an order, we must take an account of the mass heated, and of the extent of its surface which is liable to cool by contact, radiation, or both; and lastly, of the loss of conductibility due to the increase of temperature of the substance interposed. Ether, alcohol, &c., may be inflamed, and gunpowder exploded, by making the discharge through charcoal points.

Sir Humphry Davy avoided the increase of temperature in the wires through which the current was discharged by taking them of a length sufficient to discharge the number of pairs of plates employed in the pile, and thus found that the length of wire in this case is inversely proportional to the number of double plates. The diminution of conductibility due to increase of temperature he exhibited by a platinum wire made red-hot by the galvanic current; for when he raised one part of it to a white heat by means of a blow-pipe, the heat in the other parts of the wire became immediately reduced. The order of heating in metals, beginning from that most susceptible, which he has given, is as follows:—iron, palladium, platinum, tin, zinc, gold, copper, silver.

Under Electro-Chemistry will be found a statement of the relation subsisting between chemical changes and galvanic electricity. We may however in this place state some of the early results obtained.

The decomposition of water by the battery is effected by bringing the points of the positive and negative wires very near each other under water, inverted glasses being placed over them to collect the gases which are evolved. If the wires be not oxidable, then oxygen gas will be formed at the extremity of the positive wire, and hydrogen at the negative, in the same proportions in which they constitute that liquid; but if oxidable, then the positive wire will be covered with an oxide, while the negative wire still produces hydrogen gas. In general oxygen and chlorine are found at the positive pole, and the other gases at the negative; but we are not to suppose that oxygen only is disengaged by one wire, and hydrogen only by the other; for the particles of water in contact with the ends of either wire are strictly decomposed into their constituent gases, but the oxygen formed at the negative wire is transferred to the positive, and the hydrogen at the positive is transferred to the negative.

The chemical analysts were at first somewhat puzzled at finding foreign products, when producing decomposition by galvanism; soda, which was sometimes found, was due to the decomposition of small portions of the glass in which the experiments were made, and muriatic gas to vegetable substances employed occasionally, as wet cotton-thread, when the liquid was contained in separate vessels having only this mutual communication.

When neutral salts were held in solution and exposed in the same manner to the galvanic action, their alkaline bases were found at the negative wire, and the acid at the positive: thus zeolite was decomposed into soda and lime; glauber salt into solution of soda and sulphuric acid; while the metallic solutions gave their crystals and oxides to the positive pole, and transferred the acids to the negative. Davy made the remarkable discovery that this transfer took place without any combination being effected with the parts of the medium traversed, even when the latter had a great affinity for the elements which passed through it. He arranged three cups, in the first of which was a solution of litmus, in the second a similar solution, and in the third sulphate of soda. The positive wire was immersed in the first cup, the negative in the third; and the intermediate one was connected with the two extreme cups by means of a moistened thread, so as to complete the circuit: the result was, that the solution of litmus in the positive cup became red, indicating the transfer of the acid from the third cup, while the similar solution in the intermediate cup underwent no change, clearly showing that the acid in its transfer did not combine with the solution through which it passed. Similarly, upon reversing the poles, a green was produced in the first cup, while the middle still remained unaffected. But he soon recognised that there was an exception to this, namely, when the transmitted substance and the medium combine so as to form an insoluble compound; for when it has thus acquired a greater specific gravity than the medium, it is necessarily drawn out of the line of transference; and if by mechanical means it should be preserved in it, the transfer will go on as before.

It may be observed generally, with respect to chemical decompositions effected by galvanism, that it is quantity rather than intensity which is requisite, and that the metals, alkalies, and earthy bases are transferred to the negative pole; the acids, oxides, and chlorides to the positive. By the successive labours of Davy and other chemists, different substances which had before been supposed simple, as soda, potash, lime, baryta, strontia, magnesia, zircon, &c., were analysed by this powerful instrument; and though silex, alumina, &c., offered great resistance to its application, and the metallic bases were with difficulty restrained from again combining with oxygen, still in the majority of cases the analysis has been successful. The same method was applied by Brande to fluids containing albumen, when albumen and alkali were found at the negative pole, albumen and acid at the positive; he also found that though it remained fluid with a weak battery, when a stronger one was employed it was separated in a coagulated form. Experiments of the same nature were made by Golding Bird, whose results do not agree with those obtained by Brande. He used for his battery the Voltaic form, a *Couronne de Tasses* of thirty small plates, excited only by a weak solution of salt, and first operated on liquid albumen in a state of non-combination. Putting serum of blood into a glass vessel, and having introduced the wires of the battery, a cloudy deposition took place near the positive wire without adhering to it. The experiment being next made with two vessels connected by moistened cotton, coagulation took place in the positive vessel, while none occurred in the negative; after a time the contents of the former had an acid taste, and of the latter a caustic alkaline flavour: when all in the positive vessel was coagulated by the galvanic action, he found there hydrochloric acid mixed with chlorine, and the alkali in the negative vessel. He has given also an explanation of the causes of the difference in Brande's results.

An interesting class of experiments is due to Mr. Crosse on the employment of electricity, in a state of high tension, to form mineral and other substances. There is a cavern near Broomfield, of which the vault is covered with arragonite and carbonate of lime and fine crystals. The water which drips from this vault holds in solution ten grains of carbonate of lime and a little sulphate of the same to each pint. A glass filled with this water was submitted to the action of a battery consisting of 200 pairs of plates, and at the expiration of ten days the negative pole was found to have formed rhomboidal crystals of carbonate of lime, accompanied by some gas-bubbles, and in less than a month after the wire was covered with regular and irregular crystals, whence it follows that the bi-carbonate was decomposed into carbonate and carbonic acid gas. He also let the water drop on a piece of brick subjected to a current from 100 five-inch plates, the brick being supported by a funnel which conducted the water into a vessel below; after four or five months the brick near the negative pole of the battery was covered with carbonate of lime, while near the positive pole were disposed prismatic crystals of arragonite; and the same experiment being repeated with fluosilicic acid, regular hexahedral pyramids similar in all respects to quartz were obtained; those which were left in a dry place acquired sufficient hardness to scratch glass; the others had not that power, and gradually lost their transparency. In his varied experiments of this nature he succeeded in forming, by means of the galvanic battery, the following minerals:—carbonate of lime; arragonite; quartz; protoxide of copper; arseniate of copper, and its blue and green carbonates; phosphate of copper; carbonate of lead; chalcedony, &c., upon which Becquerel remarks, in his 'Experimental Electricity,' "nearly all these substances we have obtained these dozen years with the *simple* electro-chemical apparatus."

We now pass on to a brief notice of the physiological effects produced by galvanism, from which we must exclude any account of the animalculæ observed by Mr. Crosse in the solutions employed in his experiments.

In the life of GALVANI, in BIOG. DIV. [see also VOLTA] there is an account of the convulsive motions to which denuded frogs are subject when the nerve and muscle form part of the galvanic circuit. In order that an individual may receive a shock from a battery, it is advisable to moisten the hand, because the dry cuticle is a bad conductor of electricity: then, on holding one of the wires of the battery and touching the other, the shock will be received and felt in the wrists, arms, or shoulders, according to the intensity of the current; or a continued sensation, resembling the piercing of a very fine needle, will be perceived by dipping the finger in a dish containing a little water in which the wires of the battery are inserted at the same time with the finger. In both cases, if the nerves are denuded by a cut, the sensation is painful, and the pain will remain some time before it subsides. In some experiments of this kind Humboldt brought on an inflammation by applying the current to a cut. Volta has asserted that the negative wire communicates the greater pain.

A flash of light is perceived by covering the bulb of the eye with tinfoil and forming a metallic communication thence with the mouth, as for instance with a silver spoon; also Berzelius found an acid taste on dipping the tongue into a zinc vessel containing water, which was placed on a silver stand, by touching the silver with his hand so as to complete the circuit. When the negative current is communicated to the taste, it is caustic and alkaline.

When the battery is applied to a nerve of a person recently dead, and the circuit is completed, several violent motions ensue, dependent on the relative position of the nerve and muscle; thus, when the wire communicates with the phrenic nerve, the muscles of respiration are set in motion; when from the ulnar nerve to the spinal marrow is included in the circuit, the fingers are set in quick motion, and so on. Fishes are still more susceptible of this electric action than animals, and strong convulsive motions will be exhibited by a live flounder placed on a zinc dish and having a piece of copper or silver on its back, as soon as the two metals come in contact: similar effects take place with leeches, worms, and amphibious animals.

It was thought by Volta that the involuntary muscles, such as the heart, could not be thus excited, but experiment has decided against him.

When the secretion was suspended by cutting the eighth pair of nerves, Dr. Philip and several French anatomists have restored it by establishing a galvanic current through the divided part of the nerves next the stomach.

Intermittent currents have been employed in the experiments of Masson, Peltier, and Delarive. To effect this M. Masson used a toothed wheel rotating by a cord round it; its axis, supporter, and itself being all metallic: a communication is formed between this wheel and a battery in the form of a helix: the object of the teeth of the wheel is occasionally to suspend the action of the current by making the connecting rod of too great a length; hence, when the wheel is made to revolve, the galvanic current acts and is suspended alternately. By a series of intermitted discharges produced in this manner, M. Masson had the cruel pleasure of killing a cat.

It has been ascertained by Matteucci and others, that portions of muscle and nerve present different electrical states with reference to other portions of the same muscle or nerve. For example, the external portion of a muscle may bear the same relation to the internal, as platinum does to zinc in the voltaic circuit. In fact, a voltaic pile may be formed by slices of muscle arranged so that the external part of one slice may touch the internal part of the next, and so on.

P. Santi Linari drew the electric spark from the gymnotus in the following manner:—he took a glass tube of the shape of a capital U, which he partly filled with mercury; at each end was fixed an iron wire through a wooden button, and which reached very near the mercury. The apparatus being fixed with mastic on varnished wood, the ends of the wires were made to touch short platina wires terminated by laminæ of the same metal, intended to make a good communication with the different parts of the electrical fish. When the circuit was formed, a spark visible even in the daylight appeared at the place where the conductors were interrupted. This experiment he repeated in different forms. ('Biblioth. Univ. de Genève.')

M. Delarive has noticed a remarkable difference of effects in the action of Voltaic and of magneto-electric currents. When the wires of the latter were used for decompositions, but in the form of thin leaves or laminæ, there was but little disengagement of gas, and the more the lamina was plunged, the less was the gas evolved, which was not the case in the common form of the wire: this does not occur in Voltaic electricity; the same experimentalist has sought the quantity of electricity necessary to decompose a given quantity of water, and his result is that the product of the time multiplied by the intensity of the current is constant.

Let us now recapitulate the general phenomena of voltaic or electro-chemical action.

If two flat pieces or plates, one of zinc, the other of copper or platinum, be immersed, without touching each other, in diluted sulphuric acid, chemical action, as it is termed, will take place between the zinc and fluid; the water of the latter undergoing decomposition, its oxygen unites with the metal to form a protoxide, while the equivalent of hydrogen is set free, but adheres to the surface of the plate in small bubbles, which gradually coalescing into larger, detach themselves and rise to the surface from their specific levity; the protoxide combines with an equivalent of acid, forming a soluble salt, which, being consequently removed, allows of renewed and continuous action on the metal. In time however the fluid becomes saturated with the sulphate of zinc, which is then thrown down undissolved, and is also deposited on the surface of the plate, acting mechanically to prevent that intimate contact between the pure metal and the water which is essential to chemical action; this obstruction is also in some measure occasioned from the beginning by the adhesion of the bubbles of hydrogen, and consequently that action is gradually retarded and finally ceases. During this time the copper or platinum plate is perfectly inactive, neither of these metals being affected by sulphuric acid, or more properly, owing to the affinity, as it may at present be still called, between those metals and oxygen, being weaker than that which exists between the hydrogen and that element.

Under these circumstances, if a perfect communication be made between the two metals, by causing a wire soldered to the one, to touch that connected with the other, a remarkable change takes place in the phenomenon, the chemical action between the zinc and the fluid becomes more energetic, but the hydrogen, instead of being liberated at the surface of that metal, appears solely at that of the other, although not the slightest effect is produced on the copper or platinum itself; while the connecting wires will be found to exhibit, by their increased temperature and their magnetic state, the usual indications of what is termed an electrical *current* passing along them, and, as is well known, an electric spark is visible at the instant of separating the wires, provided the plates be sufficiently large.

It is now generally admitted that all chemical is connected with electrical action, and that they bear a direct relation to each other, that is, a certain constant quantity of electricity is evolved by the decomposition of each equivalent of any compound, though that quantity varies for different bodies; but it is not clearly known whether the electricity is the cause or the effect of the chemical action, they being perfectly contemporaneous and co-existent to all our means of observation. It follows therefore that the quantity of electricity varies with the extent of surfaces between which the action takes place, as well as with the nature of those surfaces; but with the same two metals and fluid this quantity depends solely on the extent of surface, that is, on the size of the zinc plate.

It has been proved by Professor Daniell that under these circumstances our power of collecting or retaining the electricity evolved from any given surface of metal, depends on the extent of that of the other, or conducting metal, for in the arrangements under consideration the copper or platinum plate simply acts in this capacity, and that this second plate cannot be too large in proportion to the former, to prevent the loss of any of the evolved electricity, which, if it do not meet with a good conductor in its immediate proximity, passes off to some other.[*] The form of our arrangements puts a limit to this inequality in the extent of surfaces of the generating and conducting metals, but a more important principle still further contracts this limit, which must be briefly adverted to.

All electrical action is most easily and consistently explained as the effects of induction [Electricity, Common; Polarity], or of an action exerted by matter, itself in a polar state, producing polarity in surrounding matter; what is commonly called an electrical current is, on this hypothesis, the momentaneous destruction and reproduction of polar forces, acting along a chain of particles sufficiently approximated to admit of the intensity of the forces in that line exceeding that produced on contiguous particles in other and lateral directions. In the voltaic circuit the particles of the fluid form a part of the chain through which the induction, originated by the zinc on the fluid, is propagated, the chemical decomposition is connected with or occasioned by this polarity, the hydrogen of one particle of water quitting its equivalent of oxygen to combine with that of the contiguous particle, and so on throughout until the hydrogen of the particles in contact with the conducting plate, having no oxygen wherewith to combine, is liberated at that surface in its gaseous state; the metallic part of the circuit undergoes no chemical change except at the surface in contact with the fluid, where the polar forces produce oxidation of the metal, and consequent decomposition of that fluid.

If this chain of polarised particles be broken, and the interposed matter be a nonconductor, the current is at once arrested, and the chemical action between the zinc and the fluid nearly ceases; but even a diminution in the conducting power of any part of the circuit occasions a diminution or retardation of that action. The fluid of the arrangement is an imperfect conductor, compared with the metallic part, and if the distance between the metals be increased, the increase of the intervening portion of imperfect conducting matter may occasion a cessation of the action, and always diminishes it in an inverse ratio to that distance. Hence the necessity in all forms of *voltaic batteries* for diminishing as much as possible the quantity of fluid between the metallic elements: consequently the magnitude of the negative or conducting plate cannot be indefinitely increased, if by so doing it becomes necessary, owing to the peculiar form of the arrangement, to increase the distance between the two plates.

Although we are warranted in inferring by analogy that there may be other chemical sources of electro-polar induction than oxidation of a metal, yet at present we are not acquainted with any other that can at all be compared with it in energy; and, of all combination by which this oxidation may be produced, the most efficient is that of a metal and a solution of a metallic salt, the acid of which has a greater affinity for the former metal than it has for that with which it is combined. If therefore a solution of sulphate of copper be used, instead of the simple diluted sulphuric acid of the arrangement, it becomes far more powerful; but this substitution necessitates a precaution to prevent the deposition on the surface of the zinc plate of the metallic copper liberated by the decomposition, which deposition would otherwise almost instantly take place, and thus, by causing both surfaces to consist of the same metal, polar currents would be produced in opposite directions, which would neutralise each other's action.

The precaution alluded to consists in interposing between the decomposing plate and the metallic solution a substance which, while it admits of the passage of the current, and even that of the pure fluid under the influence of that current [Endosmose], mechanically intercepts the solid copper; the arrangement of the "constant battery," as it is technically termed, for which we are indebted to Professor Daniell, consists of a small rod of amalgamated zinc, that is, of zinc the surface of which is coated over with mercury, placed in a membranous bag, or in a porous earthenware cylinder, filled with dilute sulphuric acid, this cylinder or bag being again placed in a copper one filled with a saturated solution of sulphate of copper; this external copper vessel constitutes the conducting plate, and has the connecting wire soldered to it, while the other wire is attached in any convenient mode to the zinc rod. It must be observed that the membrane or porous cylinder must be perfectly continuous: the least fissure would admit of the passage of the copper to the zinc, and destroy the effect.

As long as the two wires do not touch, this battery is nearly quiescent, except the slight local action which takes place between the zinc and its surrounding fluid;[*] but when the circuit is completed by making the ends of the wires touch, the action becomes energetic, the solution of the sulphate of copper is decomposed, the reduced metal being deposited on the surface of the copper vessel; it is consequently necessary to maintain the supply by adding from time to time solid sulphate to the solution, so as to keep it always saturated; for it must be distinctly understood as a fundamental principle, that, without continuous chemical decomposition and recomposition, no current or circle of electro-polar forces can be maintained.

Let the ends of the two wires, not in contact, be plunged into a liquid compound, such for example as sulphate of copper in solution, which, being an imperfect conductor, is capable of decomposition; decomposition of it will accordingly take place, and in the same direction as that in which it occurs in the fluid of the battery; that is, the copper of the solution will be determined to or precipitated on the wire connected with the zinc plate, while the other wire will be dissolved, uniting with the free acid to produce a sulphate. It may be asked how it happens that the copper wire is dissolved while the plate of that metal in the battery is not acted on, and what becomes of the hydrogen which was liberated in a free state, when dilute acid alone was employed. This apparent contradiction is explained by an attentive consideration of the constant direction of the current, and the consequences of its passing through the two portions of fluids in opposite directions as regards them. At the zinc plate the action is the same as before, but by virtue of the current-affinity the copper is determined to the conducting plate instead of the hydrogen, which plate therefore remains unacted on; in the other portion of fluid the wire connected with the copper plate becomes the analogue of the zinc, and the water undergoing decomposition at its surface, the oxygen unites with the copper of the wire to form a protoxide, which combines with the free sulphuric acid, while the copper of the sulphate is again determined in the direction of the current, in preference to the hydrogen, to the surface of the other wire.

---

[*] If a large electrical machine were provided with a small conductor, this might become charged by half a turn of the handle, and must discharge itself laterally to the nearest conductors before it could receive a fresh charge.

[*] The object of amalgamating the zinc rod is to prevent this local action, which arises from the inevitable want of perfect homogeneity in the metal; any the slightest difference in two portions of which will cause them to act as positive and negative elements of a small circuit, and a great number of these causes that action on the zinc which takes place before the great or principal circuit is completed; the perfect conducting power of the mercury appears to destroy or neutralise these partial currents, as that of the battery itself would be destroyed if the two plates were connected within the fluid by a perfect conductor, instead of having an imperfect one interposed between them.

This example explains why, during electrolytic decomposition, the elements of a compound are determined in definite directions to one or other pole of the battery: and hence the classification of those elements into *electro-positive* or *electro-negative*, or into *Cations* and *Anions*, according to the nomenclature proposed by Professor Faraday. [ELECTRO-CHEMISTRY.]

When the elements of a voltaic arrangement are single, or when it consists of a pair of plates only, the current, however abundant as regards what may be called *quantity*, is deficient in *tension*, or in that quality which pre-eminently characterises the electricity of friction: an increase of tension, as well as of quantity, is obtained by combining two or more single batteries, the copper element of the one being connected with the zinc of the next by a perfect conductor, and so on in continued succession. In constructing such compound arrangements, or batteries, it must not be inferred that the quantity and tension depend simply on the extent of the surface of the plates taken collectively, and on their number; it has been proved by Daniell, Faraday, and others, that the maximum effect is obtained from a given amount of surface and a given number of combinations, when all the plates are exactly equal; and that if one pair of the series is much larger or smaller than the rest, there will be no additional power gained in the first case, and a considerable loss in the second, nearly equal to what would have been produced if all the plates had been reduced to the size of the smaller.

The term *tension*, as applied to the property imparted to the voltaic current by compound combinations, is, perhaps an injudicious one; since it suggests the idea of some resemblance to the quality of frictional electricity alluded to, which, as will be presently stated, is not precisely the case, but that a very decided modification of the active qualities of the current is produced by these combinations is shown by the fact that the decomposition of a fluid electrolyte into its constituent elements cannot be effected by a single pair of plates, however extensive their surface; while this decomposition becomes energetic by means of a combination of four or five small batteries, the total surface of the plates of which is far less than that of the single one.

The most energetic form of small constant battery is that suggested by Mr. Grove, the elements of which are amalgamated zinc and sheet platinum, the latter being immersed in concentrated nitrous acid, while the zinc element is plunged in dilute hydrochloric acid isolated by porous chambers. The platinum is not acted on, and consequently the plates are lasting, although costly at first. The zinc is of course rapidly destroyed, as it must be in all energetic arrangements, for reasons before given.

In constructing the *science* of electricity, the mind has, as in other sciences, proceeded from first observed facts to simple generalisations, or *theory*, which have again served as guides to new observations and more comprehensive generalisations. Small as the progress yet made has been, and slight as our knowledge is, when compared with what remains to be acquired, we are warranted in concluding, from the steady adherence to the principles of inductive philosophy which has long characterised our investigations, that the present *theory* of this science will be an admitted one, divested as it is, and ought to be, of any attempt to explain ultimate causes, and limited to comprising in general expressions the combined results of past observations, to be tested by its accordance with new ones as they occur. What electricity is, or more correctly speaking, what is the nature of that unknown agent which is the cause of electrical action in the most comprehensive sense of this term, we are utterly, and probably ever shall be, ignorant; but this agent appears to be as inseparable from matter as gravitation, and polarity appears to be the consequence of its presence in an active state. It can be elicited, or brought into this active state, by different causes, and what is remarkable, it presents some striking modifications in its sensible properties, according to the cause which has immediately called it into action; it was these modifications which prevented its recognition when first obtained by chemical action, or by other than mechanical means, and caused it to be denominated *galvanism* or *voltaism*, and yet longer concealed the constant connection, if not identity, between it and magnetism.

That the ultimate cause of these modified modes of action is identical, we are warranted in inferring from the identity of the phenomena which they all produce, and from the interchangeable relation of cause and effect that exists between these various sources of electrical excitation; thus we infer that the unknown agent alluded to is the cause of electricity, voltaism, magnetism, and heat, for each of these may be produced, and each in its turn is capable of producing the others. Friction is the source of an electrical action which produces light, heat, chemical action, and magnetism, but chemical action is the most abundant source of this agent, and all these phenomena are produced more freely by it than by the others; nevertheless the presence, even in the least appreciable degree, of any one of them, warrants us in admitting the identity of the cause. Magnetism is always co-existent with the agent alluded to, but under certain conditions of direction of the electrical and magnetic polarities. Whether that agent be elicited by mechanical or chemical action, or by changes of temperature in different metals [THERMO-ELECTRICITY], and conversely by employing magnetism as the immediate exciting cause, chemical action, heat, light, and magnetism itself may be produced. [MAGNETO-ELECTRICITY.]

The most remarkable and obvious of the modifications which have been above alluded to are those which have given rise to the terms *electricity of tension*, and *current-electricity*, the former characterising frictional or mechanical, the latter chemico-, thermo-, and magneto-electricity; but it is now acknowledged that these terms are only expressive of the highest and lowest degrees of a common property. The spontaneous disruptive discharge which takes place through very imperfect conducting media, such as dry gases, from a body supercharged with frictional electricity, has never yet been produced by the most redundant quantity of chemico-electricity. Contact must be made by some good conductor before the *current* can pass; although the current will continue for a short time after that contact is again broken, but only through a small intervening space, never exceeding an inch or two, between the anode and the cathode, the continuity of the current under these circumstances being indicated by the intense arc of flame between the points terminating the connecting wires of an extensive compound battery; and in the case of thermo- or magneto-electricity it is only at the instant of breaking the contact that the spark appears, indicating the momentary transit through an unappreciable distance of the current, which is instantly arrested when that distance becomes sensible: yet that the electricity from these three sources possesses some tension has been proved by the charge imparted to a Leyden jar from a voltaic battery, and by other indications of the presence of that quality in feeble degrees, both in thermo- and magneto-electrical currents, as for example by the decomposition of solution of iodide of potassium when the anode and cathode are very near to each other.

That power to which the name of *induction* is given, and which is the consequence of the more comprehensive agency termed *polarity*, is another and universal characteristic of electrical action. [ELECTRICITY, COMMON.] The inductive power of frictional electricity and of magnetism were the earliest observed facts in the science, but it is only within a few years that the same power has been shown to accompany the other sources of excitation, owing to the low degree in which they possess it when compared with the former: but now by means of the multiplier or coil, the inductive power of the current from a single pair of plates may be made manifest, especially by the physiological action called the *electrical shock*, which thus modified cannot be distinguished from that obtained from a charged Leyden jar.

We must also glance at another source of electricity namely *vitality*. Are we yet warranted in assigning this as another effect of the same agent? This question cannot be answered; all we as yet know is, that animal electricity as exerted at volition by the Gymnotus, Torpedo, and perhaps other animals, is capable of producing induction, and therefore attraction, heat, light, chemical action, and magnetism, and the physiological action on living bodies, identically in the same manner as the electricity from inorganic sources. [ELECTRICITY OF ORGANIC BEINGS, in NAT. HIST. DIV.]

In comparing the discharge of the galvanic battery with that of the common electrical machine, we may remark that the current is a continuous succession of discharges of electricity generated and maintained by the contact and chemical action of the materials of the battery, and like the discharge of the electrical machine it may be classed under three heads, namely, the discharge by *conduction*, as when the circuit is completed by a good solid conductor; by *disruption*, when a luminous appearance is seen through a short interval of non-conducting matter; and thirdly by *convection*, which takes place in liquids, and is accompanied by chemical action, and the transfer of particles of the conductor.

When electricity, however produced, is in motion, all the particles of the conductor are concerned, in conveying the force, and not the surface merely, as in static electricity. [ELECTRICITY.] In such a case induction takes place between one transverse section of the conductor and other sections just before and behind it, while a small but sensible portion of the induction is directed to surrounding objects. If the thickness of the conductor be reduced the particles have to transmit a larger portion of the force, and the result is a considerable elevation in temperature, sufficient to ignite and even fuse the wire, a circumstance taken advantage of in firing the charge of gunpowder used in blasting. Metals degenerate in conducting power by elevation of temperature, as may be well shown by raising a platinum wire to a dull red heat, by sending a voltaic current through it, and heating a portion of the wire by means of the flame of a spirit-lamp; the temperature of the other part of the wire will decline, and the wire cease to be visible, in consequence of the increased resistance offered to the current by that part of the wire which is in the flame. A contrary effect is produced by cooling a portion of the wire in water, the reduced temperature at one point allowing more electricity to pass, as is manifest by the light given off by the wire, which may even fuse and disappear in globules.

We have stated under GALVANOMETER the method adopted for ascertaining the conducting power of metals for electricity. The following table shows the conducting power of wires of the same length and diameter, by which it will be seen that these powers vary with the temperature, the effect of a moderate rise of temperature in reducing the conducting power being considerable :—

Metals.	At 32° Fahr.	Silver at 32° Fahr., being equal to 100°.	At 212° Fahr.
Silver . . .	100·000	71·316	100·000
Copper . . .	91·517	64·919	91·030
Gold . . .	64·960	48·489	67·992
Cadmium . .	24·579	17·506	24·547
Zinc . . .	24·068	17·596	24·673
Tin . . .	14·014	8·657	12·139
Iron . . .	12·350	8·387	11·760
Lead . . .	8·277	5·761	8·078
Platinum . .	7·933	6·688	9·378
Mercury . . .	1·738	1·575	2·208

When equal amounts of electricity traverse similar wires of different metal in equal times the rise of temperature in the wire is inversely proportioned to its conducting power, so that the better the conductor, the smaller is the quantity of heat emitted by it. A compound wire formed of equal alternate portions of silver and platinum will transmit a current so as to heat the platinum links to visible redness, while the silver from its superior conducting power will not become luminous.

If a Leyden jar or battery be repeatedly discharged through a platinum wire too thick to be fused by it, the wire will become shortened as if it had been acted on by a force transverse to its length. A similar effect takes place with voltaic electricity. If a platinum wire be arranged in a porcelain trough, so that when fused it shall retain its position as a wire, and a strong current be sent through it, it will snap asunder when near the point of fusion, thus showing a contraction in length, while if a similar experiment be performed with lead wire, it will gather up in nodules which encroach on each other as if from longitudinal compression. It has also been noticed that telegraph wires which have been long in use become brittle, and it has been ascertained that while a wire is transmitting the electric current there is a temporary diminution in the co-efficient of elasticity independent of the heating effect of the current.

Liquids are greatly inferior to solids in conducting power, so much so that it is difficult to compare them. According to M. Pouillet, a platinum wire conducts 2,500,000 times better than a saturated solution of sulphate of copper. In many liquids the conducting power rapidly increases with the temperature, a result contrary to that obtained with solids. Gases are almost perfect insulators of the voltaic current.

With respect to the disruptive discharge, we have an instance of it in the fusion and dispersion in vapour of the conducting wire, when not of sufficient capacity to convey the current. By rarefying the air between the ends of the terminal wires, the space through which the discharge will take place may be increased. In the large battery of 2000 pairs at the Royal Institution, Davy obtained an arc of flame between charcoal points, 4 inches in length. In such cases there is a transfer of solid particles from one pole to the other which increases the effect. A cavity is produced in the piece of charcoal attached to the last platinum or copper plate of the battery, and a mammelated deposit is formed on the charcoal connected with the last zinc plate. Even the densest metals, such as platinum and iridium, are transferred from one pole to the other.

The discharge by convection introduces us to the beautiful and important branch of science, Electro-Chemistry, to which we refer.

GALVANISM, in its action on the human system, resembles electricity, yet it is distinguished by certain peculiarities. In its application it can be rendered more continuous and uniform, and may, like electricity, be administered either in shocks, or in a regular flow of galvanic influence through the body. It possesses more power over the chemical actions of the body than electricity, and promotes more completely those processes of decomposition and recomposition which take place in the living frame, as well as the functions of organic life, than common electricity. But the chief distinction consists in the difference of action of the two poles. Each pole excites peculiar phenomena in the organs to which it is applied. This difference is less perceptible when mere shocks are administered, than when a continuous stream of galvanic influence is transmitted from one point to another of the body. The positive pole more particularly influences the muscular and vascular system, while the negative pole more especially affects the nervous system. At the positive pole there is felt the shock, strong movements, a feeling of concentration and contraction, increased warmth and mobility of the part, with gradual diminution of the secretion and sensibility. At the negative pole the pain and sensibility are stronger and more acute, the organ expands, is more irritable, while the muscular action and mobility are lessened. The difference of their action on the secreting powers is best seen by applying the respective poles to a surface which has been recently deprived of its cuticle, such as where a blister has been. The positive pole changes the serous secretion into that of lymph, which at last becomes thready; the part dries and is inflamed. The negative pole causes an abundant secretion of a dark-coloured, highly acrid fluid, which excoriates the skin over which it flows; the part also experiences an enduring irritation. Atonic swellings are rendered harder, should they not become inflamed by the positive pole, while frequently by the negative pole they are dispersed and resolved. Notwithstanding the possession of such powerful properties, galvanism has not produced so valuable results in medicine as might have been anticipated. This comparative failure is no doubt to be attributed to errors in the mode of applying it. As the diseases in which it has been recommended are those already enumerated under electricity [Electricity, Medical uses of], it is not necessary to repeat them here. It may be proper however, to remark, that it was urgently recommended during the prevalence of the Asiatic cholera, but the results were not satisfactory. Like many other powerful agents, it was not used till a very late stage in the complaint, when recovery was almost impossible. It is also to be doubted whether galvanism be at all applicable to cholera, since it appears that the continued application of it causes death, by inducing inflammation of the lungs, in cases of animals where the eighth pair of nerves have been divided, more speedily than where the same nerves have been divided in animals to which the galvanic power was not applied as a substitute for the nervous. Inflammation is the invariable consequence of the application of the positive pole; while the negative pole would cause a flow of acrid secretion which could not benefit the patient. The identity of electricity, whether common or galvanic, with the nervous power, is much to be questioned, but on this subject Matteucci has entered at some length in his numerous papers. (See Delarive's 'Electricity;' and the controversy between Dr. W. Philip, Dr. Williams, and others, in 'Medical Gazette,' vol. xvii.)

The part to which the poles are applied requires to be moistened, where a slight effect is wished, with plain water; but when more powerful effects are wished, with salt and water.

GALVANO'METER, or MULTIPLIER, is an instrument constructed for the purpose of detecting the presence of feeble electro-chemical currents. The nerves and muscles of newly killed frogs were at first used; but the discovery of electro-magnetism has furnished a more delicate and measurable criterion: the instrument founded on this principle has been successively improved in the hands of Schweigger, Cumming, Nobili, and Melloni, to a most remarkable degree of delicacy.

The principle of the construction depends on the property possessed by electrical currents of acting on magnetised needles; for if the conducting wire be placed on the magnetic meridian above or below the needle, the latter will suffer a deviation to the right or left according to the direction of the current. [Electro-Magnetism.]

The action of terrestrial magnetism tending to restore the needle, after its derangement by the current, to its original position, is almost entirely corrected by employing two similar needles supported parallel to each other by a light piece of straw or other substance, and placed with the poles of one in an inverse position to those of the other. A pair of needles thus arranged forms what is termed an *astatic* combination, (from *αστατος*, indifferent.) The needles are delicately suspended by means of a thread of untwisted silk or a filament of glass in such a way that the lower needle shall be within a coil of copper wire covered with silk or cotton, and making several hundred convolutions. In such an arrangement the needle which is outside the coil will be acted on by the upper wires only, the lower ones not being sufficiently near to produce any effect: and this action coincides with their action on the lower needle with its reversed poles, so that the effect of a feeble current is materially increased. The apparatus is usually inclosed within a glass case, and there is an adjusting screw at the point of suspension for raising or lowering the silk, so that when the instrument is not in use the needles can be let down so as not to drag upon the suspending fibre. Over the coil, but below the upper needle, is a sheet of copper, graduated so as to show the angular deviation of the needles. There are also binding screws for connecting the ends of the coil with the wires which transmit the current. There are also levelling screws and a lever for placing the coil parallel with the needles so as to make them coincide with the zero of the graduated circle. Thus the galvanometer not only indicates the presence of voltaic action, but estimates its amount. When the needle does not deviate more than 15° or 20° the amount of force may be considered as accurately represented, but for larger angles such is not the case, since the more the needle deviates from parallelism to the wire the more obliquely and consequently less powerfully does the force act. For example, more force is required to move the needle from 20° to 25°, than from 10° to 15°; but as the deviation in each case is definite for the same instrument the measurements may be so far relied on.

M. Becquerel's *Differential Galvanometer* consists of two insulated copper wires of equal length and diameter surrounding the needles, forming two independent circuits, and having four terminations instead of two. This instrument was used for estimating the conducting power of the different metals for electricity which varies nearly in the same order as their power of conducting heat. Now it is evident that if two equal currents were sent in opposite directions through the two coils of the above instrument they would neutralise each other in their action on the needle which would remain undeflected; but if one current were stronger than the other there would be a corresponding deviation of the needle. In using the instrument a small voltaic battery was connected with it, with two wires from each pole so as to divide the current into two equal portions, one of which was transmitted through one of the coils, and the other through the second coil in an opposite direction. When wires of different metals were introduced into the two circuits, a wire of inferior conducting power would show a diminution in the current and a deflexion of the needle, but equilibrium was restored by varying the length of one of the wires, and by comparing the lengths of the wires thus introduced their relative conducting powers were arrived at. With this instrument, assisted by Wheatstone's *rheostat*, the conducting powers of a number of wires of different metals were accurately ascertained.

There are various instruments with various names used for measuring, directing, or reversing the voltaic current. Some writers do not content themselves with so simple a word as *Galvanometer*; but use other and more recondite terms, and often so copiously that scientific nomenclature, like diplomatic speech, seems to be intended *pour cacher la pensée.* For example, an apparatus used for generating a voltaic current is no longer called a *battery*, but a *Rheo-motor*, from ῥέω to flow, and *moveo* to move, while the wire which conveys the current is called the *rheophore*, from ῥέω and φορεω to bear. The whole circuit is also called the *rheophoric* circuit, while the instrument which detects the existence of an electrical current is called, instead of a *galvanoscope* a *rheoscope*, from ρεω and σκοπεω to see. If used for measuring the current it is not called a *galvanometer* but a *rheometer*. The little instrument used for reversing the currents is called a *rheotrope* (τρεπω to turn); that for periodically interrupting the current is a *rheotome* (τεμνω to cut off); while that for maintaining the current at any degree of force is a *rheostat* (σταω to stand or remain). The reader will find these instruments described in Harris's 'Rudimentary Treatise on Galvanism,' 1856.

GAMBIR. [TANNIC ACID.]

GAMBIT. [CHESS.]

GAME-LAWS were the remnant of the ancient forest-laws, under which the killing one of the king's deer was equally penal with murdering one of his subjects; or, as Sir W. Blackstone somewhat quaintly expresses it, "from this root has sprung a bastard slip, known by the name of the game-law, now arrived to and wantoning in its highest vigour, both founded upon the same unreasonable notion of permanent property in wild creatures, and both productive of the same tyranny to the commons; but with this difference,—that the forest-laws established only one mighty hunter throughout the land, the game-laws have raised a little Nimrod in every manor." Some portion of the history of the game-laws in England will be found under FOREST LAWS, and WARREN, FREE.

These laws decided what birds and beasts should be deemed game, prohibited all persons not duly qualified by birth or estate from killing any such prohibited creatures, or even from having them in their possession as articles of food, and inflicted severe punishments and penalties upon the offenders against their provisions.

By the last general statute on the subject (2 Wm. IV. c. 32), game is declared to include hares, pheasants, partridges, grouse, heath or moor game, black game, and bustards. Snipe, quail, landrail, woodcocks, and conies are not game.

The statute 13 Richard II. c. 13, the title of which was, "None shall hunt but they who have a sufficient living," was the first introduction of a qualification to kill game. This statute prohibited laymen who had not lands or tenements of 40*s.* a year, and priests who had not 10*l.* a year, from taking or destroying deer, hares, or conies, upon pain of one year's imprisonment. By 3 Jac. I. c. 13, the qualification to kill game was increased to 40*l.* a year in land and 200*l.* in personal property. By 22 & 23 Car. II. c. 25, the qualification was limited to persons who had an estate of inheritance of 100*l.* per annum or an estate for term of life or 99 years, or upwards, of 150*l.* annual value. On this Blackstone remarks, there was "fifty times the property required to enable a man to kill a partridge as to vote for a knight of the shire." Qualifications were also of a personal nature, as being the son and heir-apparent of an esquire. Persons who had not these qualifications were not allowed to have or keep game-dogs. After repeated discussions in and out of Parliament, by the statute 1 & 2 Wm. IV. c. 32, the necessity of any qualification for the killing of game was abolished, and the right was made to depend simply on the payment of an annual tax, called a game certificate.

Certificates were first required to be taken out by persons qualified to kill game by the act 25 Geo. III. c. 50. The certificate itself, which costs 3*l.* 13*s.* 6*d.*, must be taken out annually, and it expires in July. A sportsman who refuses to show his certificate when demanded by collectors of taxes, gamekeepers, landlords, occupiers, and lessees, is liable to a penalty of 20*l.* Uncertified persons who kill or take any game, or who use any dog, gun, &c., for the purpose of searching for, or killing, or taking game, are liable, on conviction before two justices, to a penalty not exceeding 5*l.* for each offence, with additional penalties under the Certificate Act of 23*l.* 13*s.* 6*d.* Certificates are required not only to enable persons to kill game, but also woodcocks, snipes, quails, landrails, or conies (except by the proprietors of warrens or of any inclosed ground whatever, or by the tenant of any land, either by himself or any person by his direction or command).

By the statute 11 & 12 Vict. c. 29 (1848), reciting that "it has been found that much damage has been and is continually done by hares to the produce of inclosed lands, and that great losses have thereby accrued and do accrue to the occupiers of such lands," power is given to persons in the actual occupation of inclosed lands, or the owners, who have the right of killing game thereon, to take, kill, and destroy hares themselves, or by some person authorised by them in writing, without a game certificate. The same statute authorises persons to course or hunt hares without a certificate.

The right which a certificate gives to kill game is subject to a number of restrictions. A certificated person is liable to a penalty of 5*l.*, with costs, for taking or killing game on Sunday or Christmas-day, and to a penalty not exceeding 20*s.* for each head of game taken or killed at the season when the pursuit of each kind of game is prohibited. The certificate, of course, does not confer any right to enter on land to kill game except where there is a right by ownership or permission so to enter. The certificated person is still subject to the general law of trespass for going upon another person's land.

The right to the game is vested, by 1 & 2 Wm. IV. c. 32, in the tenant in all cases where it is not reserved to the landlord in his agreement with the tenant; but the game is generally coveted by the landlord, and few tenants are in a situation to oppose their landlord. The consequence is that the game is reserved by the landlord when he lets his land; and when this is the case, the occupier can neither kill game nor give permission to another person to do so, and he is liable, under 1 & 2 Wm. IV. c. 32, to a penalty of 20*s.*, with costs, for every head of game killed by him or other persons authorised by him. When the landlord reserves the game, he may not only himself kill it on the tenant's land, but he may authorise any certificated person to enter on the land and kill it. The person who has the right of killing the game, or the occupier of the land, or gamekeepers, or any person authorised by either of them, may require a person found trespassing in pursuit of game to quit the land, and to give his name and place of abode; and in case of refusal, the trespasser may be taken instantly before a magistrate, who may fine him 5*l.*; but if not brought before a magistrate within twelve hours, proceedings must be taken by summons or warrant. If five or more persons together trespass in pursuit of game, and any one of them be armed with a gun, and if threats or violence are used to prevent any authorised person from approaching them for the purpose of requiring them to quit the land, or to tell their names and abodes, every person so offending is liable to a penalty not exceeding 5*l.*, in addition to any other penalty, with costs.

The law is very severe against persons not authorised, who take or destroy game by night. By 1 & 2 Will. IV. c. 32, "day-time" is to be deemed from one hour before sun-rise to one hour after sun-set. The 9 Geo. IV. c. 69, enacts, that if any person by night shall take or kill game or rabbits on any land, or shall enter therein with gun, net, engine, or other instrument, for the purpose, he shall, on conviction before two justices, be committed to hard labour in the house of correction for a term not exceeding three months, and, at the expiration of that period, find securities for twelve months, himself in 10*l.* and two others in 5*l.* each, or one security in 10*l.* In case of not finding sureties (and it is not a likely case that night-poachers should be able to find them), the offender may be further imprisoned six months. For a second offence the term of imprisonment is extended to six months, the sureties are doubled, and required for a period of two years. If the offender cannot find sureties, he may be further imprisoned for twelve months. The third offence was punishable with transportation for seven years, now penal servitude, or imprisonment with hard labour in the house of correction for a term not exceeding two years. Offenders under this act may be apprehended on the spot by owners and occupiers of land, their servants and assistants; and if they assault or offer violence with gun, club, stick, or otherwise, they are liable to penal servitude for seven years, or to be imprisoned with hard labour for two years. The punishment for night-poaching is still more severe when three or more persons enter any land for the purpose of taking or destroying game or rabbits, armed with a gun, bludgeon, or other offensive weapon (and sticks and stones may be offensive weapons) and they are subject to penal servitude for a period not exceeding fourteen years, or to imprisonment with hard labour for not exceeding three years. In 1844 an act was passed (7 & 8 Vict. c. 29) which extended the provisions of 9 Geo. IV. c. 69, against night-poaching to persons who take or kill game or rabbits upon public roads or highways, and other roads and paths leading to enclosed gates, and also at the gates, outlets, and openings between such lands and roads or paths.

By s. 36 of 1 & 2 Wm. IV. c. 32, it is enacted, that if any unauthorised person be found by day or night on any land in search of game, and have in his possession any game which "appears to have been recently killed," any authorised persons, as gamekeepers, occupiers, or others who have the right of killing the game, may demand such game and seize it if not immediately delivered.

A penalty not exceeding 10*l.* is incurred for laying poison with intent to destroy game (1 & 2 Wm. IV. c. 32).

If any person who is not authorised to kill game himself, or who has not permission from a person who has such right, shall take out of the nest or destroy the eggs of any bird of game, or of any swan, wild duck, teal, or widgeon, or shall knowingly have in his possession any such eggs so taken, he shall be liable on conviction to a penalty not exceeding 5*s.*, with costs, for each egg (1 & 2 Wm. IV. c. 32, § 24).

By the act 7 & 8 Geo. IV. c. 29, it is felony to course, hunt, snare, carry away, kill or wound, or attempt to kill or wound, any deer kept in any inclosed land, whether forest, chace, or purlieu, or other place wherein deer is usually kept. The punishment is now penal servitude for seven years, or imprisonment for two years. If the offence be committed in the uninclosed part of a forest, chace, &c., the penalty for the first offence is a sum not exceeding 50*l.*; and for a second offence, penal servitude or imprisonment.

Such are the principal legal provisions respecting game which exist at the present day. The right of appointing persons called gamekeepers, who are, properly speaking, a game police, does not belong to all owners of lands. Gamekeepers were first allowed to be appointed by 22 & 23 Car. II. c. 25. Before the act 1 & 2 Wm. IV. c. 32 was passed, a person could only appoint one gamekeeper. By this act lords of manors may appoint one or more gamekeepers to preserve or kill game within the manor for their own use. Lords of manors may depute any person to be a gamekeeper to a manor, with authority to kill game for his own use or that of any other person named in the deputation. The gamekeepers are authorised to seize all dogs, nets, and other engines used for killing game by uncertificated persons.

Until the passing of the act 1 & 2 Wm. IV. c. 32, no person was allowed to sell game; but it was made saleable by this act, as the law was systematically evaded. A dealer in game must obtain an annual licence from the justices, who hold a special session in July for the purpose of granting such licences. Innkeepers, victuallers, retail beersellers, guards, coachmen, carriers or higglers, or persons in the employ of any of these classes of persons, are prohibited from dealing in game. Licensed dealers who buy game of any person not authorised to sell it are liable to a penalty of 10*l.* with costs. A person not being licensed, who buys game of an unlicensed person, subjects himself to a penalty not exceeding 5*l.* for each head of game, with costs.

The preservation of game is an object of constant solicitude to nearly all those who belong to the landed gentry in this country. The pursuit of game is not only followed for the sport which it affords, but because ideas derived from the feudal times still attach a social distinction to the right of killing birds and beasts of game. Although a property qualification has been abolished, the privilege is still sufficiently restricted to confer upon those who enjoy it a petty importance. Within the last century game has been preserved to an excess which was previously unknown. Most of the laws relating to game which have been passed within this period have been made to enable game-preservers to indulge in this taste, and to visit with greater severity those who are tempted by the abundance of game to become poachers. The accumulation of game in preserves, watched and guarded by numerous keepers, has led to changes in the modes of sporting. The sportsman of the old school was contented with a little spoil, but found enjoyment in healthful recreation and exercise, and was aided by the sagacity of his dogs. In the modern system of battue-shooting, the woods and plantations are beaten by men and boys; attendants load the sportsman's guns, and the game is driven within reach of gun-shot, and many hundred heads of game are slaughtered in a few hours. The true sportsman would as soon think of spoiling a poultry-yard. Battue-shooting is the end of excessive game-preserving; and in this so-called sport, members of the royal family, ministers of state, and many of the aristocracy, eagerly participate. In an ordinary day's sport of this description, seven or eight hundred head of game may be killed by three or four sportsmen in about four hours, and perhaps fifty or sixty wounded may be picked up on the following day. A couple of gentlemen may kill nine hundred hares in one day. On a great field-day, when the sportsmen are more numerous, the slaughter is immense. Whole waggon-loads of hares are sent off to the London and other great markets for sale, as the result of one day's sport.

The effect of protecting game by oppressive laws is, perhaps, more injurious to the morals of the rural population than any other single cause. With a densely crowded population, thousands of whom are often pressed by hunger, and frequently in a state of the most lamentable poverty, the temptation to kill game is irresistible. It swarms before the labourer as he returns home in the evening from his long day of hard toil. *He* does not recognise property in game. No man can claim an individual hare or partridge like an ox or a sheep. The latter must be fed at the expense of their owners; but game is fed by no one in particular. This man, then, who probably would not, for all his poverty, violate the laws of property in the case of poultry, and who recognises no greater right of property in a partridge than in a sparrow, sets a snare in the haunts frequented by game near his cottage, and is pounced upon by the keeper. When he comes out of the jail, the farmers perhaps dare not employ him, lest they should offend the game-preservers their landlords. The justice and the rural police look upon the jail-bird with suspicion; and only at the beer-shop, with men of his own stamp and character, does he feel at home. It is hardly necessary to sketch his further progress. In nine cases out of ten, it is from bad to worse; and this because for objects of selfish gratification men have given to a bird or beast of little worth in itself an arbitrary value, and protected it by statutory regulations stricter than are applied to many other things which are recognised as objects of property by all mankind.

Jails require to be enlarged; and as poaching leads to other crimes, a more extensive police is required for the protection of property. The game laws are in this way a heavy burden on the occupiers of land.

Game, and the game laws, are among the greatest hindrances to the improvement of agriculture. They not only prevent a gain, but they occasion a loss to the actual aggregate of agricultural products.

Many landowners in their enthusiasm respecting game take means to ensure its preservation which none but tenants in a wretched state of dependence would submit to. The tenant is not allowed to use his best skill in the application of his own capital to the land, but is interfered with on account of the game. This game devours the produce of the land, is fattened at the tenant's expense (compensation for the destructiveness of game being generally futile and deceptive), and the landlord pockets the money which the game thus fed produces in the market. The effect would be far less injurious if the landlord turned a certain proportion of his oxen and sheep to feed with those which belong to his tenants. There are instances where the landlord lets the game on the tenant's land to a third person, and thus gets two rents, one for the land, and another rent for the game after it has been fed by the farmer.

It has often been stated, that from three to five hares eat and destroy as much as would keep one sheep. On many farms the number of hares averages at least two per acre; and the destruction by hares alone is often equal to an additional rental of 10*s.* per acre on the whole of the farm: there is, besides, the waste and destruction caused by rabbits, pheasants, and partridges. On some farms of 500 acres where the game is strictly preserved, but not excessively, the loss caused by hares will often amount to above 200*l.* The landlord sells the hares at perhaps 1*s.* 6*d.* each, and pockets 75*l.* This is shortsighted enough, setting aside the bad moral effect of the practice. The operations of the poacher, if he escape detection, are in one sense beneficial to the tenant-farmer, for the destruction of the game adds to the farmer's profit; but if the poacher be convicted and sent to jail, then the support of the man and his family adds to the loss which the game occasions.

Many of the reservations and covenants in leases in relation to game are fit only for the copyholders of a manor four or five centuries ago. There are many farms on which the tenants are forbidden either to mow wheat or drill turnips. Mowing costs less than reaping, and the tenant has besides the advantage of an extra quantity of straw for the stock and for manure; but then the ground is left too bare to shelter the partridges, and therefore the scythe must not be used, nor any other instrument which cuts lower than twelve inches. Drilling turnips is now an essential operation in all good systems of farming; but though it gives a much greater weight of roots per acre, it encourages the birds to run, and spoils sport. In some districts, where game is preserved with great strictness, a farmer is not allowed to sow winter tares. To drain land where rabbits are kept would be a waste of property. Legislation cannot produce any improvement in this state of things. It arises from the dependent condition of the great majority of the tenant-farmers; and if a law were passed which gave them the right to kill the game on their lands, it would be of no advantage to them. The gamekeepers and other retainers of the great and small game-preservers are spies on the tenant, and in the intense competition for farms he dare not contravene the wishes of his landlord. Public opinion may and does produce some effect on the landlord's exercise of his power, but this is confined to isolated cases.

The administration of the game-laws in England is in the hands of persons who are either game preservers themselves, or who, generally speaking, are not unfavourable to the system, and hence the rigour with which offences against the law are visited. Before the act 1 & 2 Wm. IV. c. 32 was passed, penalties for infractions of the game-laws could be recovered before one justice; but now conviction can only take place before two justices, and an appeal lies to the quarter-sessions, but a certiorari is not allowed.

The number of certificates taken out annually to kill game is about 30,000 in Great Britain, and the number of licences to sell game about 800.

In other countries, as well as in England, game-laws have been an instrument of oppression. In France before the first Revolution there were edicts for preserving game which "prohibited weeding and hoeing, lest the young partridges should be disturbed; steeping seed, lest it should injure the game; manuring with night-soil, lest the flavour of the partridges should be injured by feeding on the corn so produced; mowing hay, &c. before a certain time, so late as to spoil many crops, and taking away the stubble which would deprive the birds of shelter." ('Arthur Young's Travels in France in 1787-88-89.') The tyranny of the manorial courts rendered it hopeless to escape from this oppressive system. The Constituent Assembly abolished this exclusive "droit de la chasse" which the seigneurs arrogated to themselves. A stringent game-law has nevertheless been since enacted in France.

GAMING, or GAMBLING, is an amusement,—or we might properly call it a vice,—which has always been common in all civilised countries and among all classes, but more particularly the rich and those who have no regular occupation. But a passion for gaming is not confined to the nations called civilised: wherever men have much leisure time and no pursuit which will occupy the mind and stimulate it to active exertion, the excitement of gaming, which is nothing more than the mixed pleasure and pain arising from the alternations of hope and fear, success and failure, is a necessity which all men feel, though in different degrees according to the difference of temperament. The Germans, says Tacitus, stake their own persons, and the loser will go into voluntary slavery, and suffer himself to be bound and sold, though stronger than his antagonist; and many savage nations at the present day are notoriously addicted to gambling.

Gaming (*alea*) among the Romans was played with dice. The earliest enactment against it is referred to by Plautus and Cicero; but it is not certain what the penalty was. Under the later republic and the empire gaming was a common vice, but it was considered to be disreputable. The little that is known of the penalties against gaming is contained in the Digest (11, tit. 5) and the code of Justinian (iii. tit. 43). The prætor in this, as in many like cases, placed the encourager of gaming under disabilities. If a man lent his house for gaming, and, while the gaming was going on there, was beaten or had anything stolen from his house, the prætor refused him all remedy. A senatusconsultum, the name and time of which are not mentioned, prohibited all playing for money, except the stake was made upon the five athletic exercises enumerated, and, as we must infer, by the persons who joined in the exercises. If a slave, or a son in the power of his father, lost money at gaming, the father or owner of the slave might recover it. If a slave won money, there might be an action for it against the master; but the demand against the master could not exceed the amount of the slave's peculium,—that is, the property which the slave held as his own, according to Roman custom, with the permission of his master. The prætor's edict also allowed an action against parents and patrons in respect of money lost (to children or the patrons' freedmen, as we must understand it). Justinian made several constitutions against gaming. A man who lost money at gaming was not bound to pay it; and if he did pay, it could be recovered by him or his successors (in the Roman sense) from the winner or his heredes any time within thirty years. If they did not choose to recover it, the father or defender (defensor) of the town in which the money was lost might recover it, or any other person might. The money, when recovered, was laid out for public purposes. Gamblers were also liable to a fine. Spiritual persons who violated the gaming laws, or were present at gambling, were suspended for three years and confined in a monastery. ('Novell.' 123, c. 10.)

In England, gaming was very early the subject of penal enactments, but as a proof how futile legislative measures may be, we need only mention, and we do so without fear of contradiction, that there are, or at least were, until recently, more of those infamous places of resort, appropriately denominated "hells" in London, than in any other city in the world. The handsome gas lamp and the green or red baize door at the end of the passage (as well known a sign as the Golden Cross or Spread Eagle) were recently conspicuous objects in the vicinity of St. James's, and of St. George's, Hanover Square.

It appears that the playing at cards, dice, &c., was not punishable at common law; and an action might be maintained at law for money won at play; for the contract was not void in itself, and the winner's venturing his money was a sufficient consideration to entitle him to the action.

But if a person was guilty of cheating, as by playing with false dice, cards, &c., he might be indicted for it at common law and punished by fine or imprisonment (2 Bac. Abr. 620). All common gaming-houses were nuisances in consideration of law. By the statute of 33 Hen. VIII., c. 9, "no person shall for his gain, lucre, or living, keep any common house, alley, or place of bowling, coyting, cloyth, cayls, half-bowl, tennis, dicing-table, carding, or any unlawful game, then or thereafter to be used, on pain of forfeiting 40*s.* a day;" and the same statute enacted that *every* person haunting and using the said houses, and playing, shall forfeit 6*s.* 8*d.*

By 16 Charles II. c. 7, any person who won any sum of money by fraud, cosenage, or deceit, was to forfeit treble the value won. Under the statute 8 & 9 Vict. c. 109, repealing the statute of Henry VIII. so far as relates to the prohibition of games of skill therein mentioned, together with the statutes of Charles II., and Anne, and several others, cheating at play is punished as obtaining money under false pretences.

By 9 Anne, c. 14, any person who "at any *one time or sitting*, by playing at cards, dice, or *other game whatsoever*, or by betting on the sides of such as do play," *lost* to any one or more persons, in the whole the sum or value of 10*l.*, and paid the same or any part thereof, might within three months sue for and recover the same in any court of record, and after three months any other person might sue for and recover the same and treble the value thereof, with costs of suit. It is curious that gambling in the palace where the sovereign is residing for the time being is excepted from the statute of Anne.

An act 5 & 6 Wm. IV., c. 41, repealing several old statutes, altered the law relating to securities given for gaming transactions. It enacts that in case any person shall make, draw, or execute, any note, bill, or mortgage for a gaming debt, and shall actually pay to any indorsee, holder, or assignee of such note, bill, or mortgage, the sum thereby secured or any part thereof, such money shall be deemed to be paid on account of the person to whom such note, bill, or mortgage was originally given (upon the illegal consideration), and shall be deemed to be a debt due from such last-mentioned person to the person who shall so have paid such money, and shall be recoverable by action at law in any court of record.

The acts 8 & 9 Vict. c. 109, and 17 & 18 Vict. c. 38, greatly facilitate proceedings against any common gaming-house. The first mentioned statute enacts that in default of other evidence it shall be sufficient to prove that a house or place is kept or used for playing therein at any unlawful game, and that a bank is kept there by one or more of the players exclusively of the others, or that the chances of any game played therein are not alike favourable to all the players, including among the players the banker or other person by whom the game is managed, or against whom the other players stake, play, or bet; and every such house or place shall be deemed a common gaming-house. It is not necessary under this act to prove that any person found playing at any game was playing for any money, wager, or stake. The act dispenses with the necessity of obtaining the allegation of two householders that any house is a common gaming-house; and empowers justices of the peace in places beyond the metropolitan police district, to authorise constables, and commissioners of police, within such district, to authorise superintendents by a written order to enter any suspected house or room with constables, and, if necessary, to use force for the purpose of effecting such entry, whether by breaking open doors or otherwise, and to take into custody all persons who shall be found therein, and to seize and destroy all tables and instruments of gaming found in such house or premises, and also to seize all money and securities for money found therein. If any cards, dice, balls, counters, tables, or other instruments of gaming used in playing any unlawful game be found in any house or room which the police have entered as a suspected gaming-house, or about the person of any of those who shall be found therein, it is evidence, until the contrary be made to appear, that such house or room is used as a common gaming-house, and that the persons found in the room where such instruments of gaming shall have been found, were playing therein, although no playing was actually going on in the presence of those who made the entry. Before this act was passed, persons found in a gaming-house could not be searched; and proof of play was necessary before entry. Notwithstanding this act, the keepers of gaming-houses contrived by fortifying the entrances, and by other means, to keep out the officers of justice until the instruments of gaming were removed or destroyed, so that no sufficient evidence could be obtained to convict the offenders. To render the law more efficient in this and other respects, the act 17 & 18 Vict. c. 38, was passed (1854), by which penalties and imprisonment was imposed on persons obstructing the duty of constables, and obstructing their entry made evidence of the house being a common gaming-house. Persons who have been concerned in unlawful gaming and who give evidence on the trial of any owner or keeper or person who has had the management of a common gaming-house, may obtain a certificate from the magistrate or judge of the court, which frees them from all criminal prosecutions, penalties, &c.

The punishment which may be inflicted on gaming-house keepers is, a penalty not exceeding 500*l.*, or imprisonment with or without hard labour for a term not exceeding twelve months.

By 8 & 9 Vict. c. 109, public billiard and bagatelle boards are not to be kept without a licence, and the places where they are kept may be visited at any time by constables and officers of police; and such places are to be closed entirely on Sundays, and on other days at midnight, except Saturday, when the hour of closing is fixed at eleven o'clock.

Gambling is nevertheless carried on in the metropolis at those places where billiard-tables are kept, at public-houses, and also at cigar-shops. The evidence taken before the select committees on gaming in 1844, contains a mass of information on the subject of gaming and gambling both in London and elsewhere.

In England, before the passing of 8 & 9 Vict. c. 109, the law considered wagers in general as legal contracts, and the winner of a wager could enforce his claim in a court of law. The exceptions to this rule were, where the wager was an incitement to a breach of the peace or to immorality; where it affected the feelings or interests of third persons, or exposed them to ridicule or inconvenience; or where it was against sound policy or prohibited by statutory enactment. In cases not comprehended within the above exceptions, the judges frequently refused to try actions respecting wagers, when they considered the matter to be of a frivolous or of an improper nature.

In Scotland the courts followed an opposite rule to that which prevailed in England. They held that "they were instituted to try adverse rights, and not to determine silly or impertinent doubts or inquiries of persons not interested in the matters in question;" and they decided "that their proper functions are to enforce the rights of parties arising out of serious transactions, and not to pay regard to *Sponsiones ludicræ.*"

The provisions of the statute of Anne, so far as they applied to bets exceeding 10*l.*, was so much a dead letter, that its existence appears to have been almost forgotten, until in 1843 a number of actions were brought by common informers against several noblemen and gentlemen who had violated the law by betting sums of more than 10*l.* on horse-races. A bill was brought in for the relief of these persons, and was rapidly passed through its several stages. Select committees were appointed in both Houses of Parliament to inquire into the laws respecting gaming, and another act (7 Vict. c. 7) was passed to indemnify witnesses implicated in gaming transactions who should give evidence before these committees.

The committee of the House of Commons, in 1844, on gaming, recommended that "wagering in general should be free and subject to no penalty;" and they also expressed an opinion in favour of the law of England being assimilated to that of Scotland.

In the session of 1845 the act 8 and 9 Vict. c. 109 was passed, which enacts "That all contracts or agreements, whether by parole or in writing, by way of gaming or wagering, shall be null and void; and that no suit shall be brought or maintained in any court of law or equity for recovering any sum of money or valuable thing alleged to be won upon any wager, or which shall have been deposited in the hands of any person to abide the event on which any wager shall have been made: provided always, that this enactment shall not be deemed to apply to any subscription or contribution, or agreement to subscribe or contribute, for or toward any plate, prize, or sum of money to be awarded to the winner or winners of any lawful game, sport, pastime, or exercise."

The act 8 & 9 Vict. c. 109 repealed those parts of 9 Anne c. 14, and 18 Geo. II. c. 34, which rendered it illegal to win or lose any sum exceeding 10*l.* at play or by betting.

By 5 Geo. IV., c. 83, persons betting, &c. in any street or open and public place, are punishable summarily as rogues and vagabonds.

By the 10 & 11 William III. c. 17, lotteries were declared public nuisances, and by several subsequent acts they have been prohibited under various penalties.

The act 7 Geo. II. c. 8, which was made perpetual by 10 Geo. II. c. 8, entitled "An Act to prevent the infamous practice of stock-jobbing," is violated hourly on the London Stock-Exchange by the practice of time-bargains.

The acts 19 Geo. II. c. 37, and 14 Geo III. c. 48, are intended to prevent transactions of the nature of gaming or wagering on policies of marine and life insurance.

It was enacted by the 13 Geo. II. c. 19, that no horse-race should be run for any prize of less than 50*l.* in value; and any wager on a horse-race made illegal by this statute was illegal also; but this provision was repealed by the 3 & 4 Vict. c. 5. The effect of the repeal of the provisions of this statute, and of the 33 Hen. VIII. c. 9, combined with the exception in the 8 & 9 Vict. c. 109, was to place all bargains relating to horse-racing on the same footing as other contracts. No sooner, however, were contracts as to horse-racing legalised, than a great number of petty gaming-houses sprung up, under the name of "betting-offices." The demoralisation which was found to be the immediate result called for the interference of the legislature, and the stat. 16 & 17 Vict. c. 119 was accordingly passed, expressly for the suppression of these haunts of vice.

It may be observed that, under the Bankrupt Laws, a bankrupt is not entitled to a certificate, or the certificate if granted is void, if he has lost 20*l.* in one day, or 200*l.* in a year, by any sort of gaming or wagering. (Kerr's 'Blackstone.')

In France, and many other parts of the Continent, the government not only allowed, but derived a considerable revenue from games of chance. In Paris, the *exclusive* right of keeping public gaming-houses was, until the year 1838, let out to one company, who paid an annual sum of 6,000,000 francs (about 240,000*l.*) for the privilege. They kept six houses, namely, Frascati's, the Salons, and four in the Palais Royal. In a trial in Paris, it came out in the course of the evidence, that the *clear profit* for 1837, exclusive of the duty, had been 1,900,000 francs (76,000*l.*), of which three-fourths was paid to the city of Paris, leaving the lessee 19,000*l.* for his own share. The average number of players per day was stated at 3000, and about 1000 more were refused admittance. The games played were chiefly Roulette and Rouge-et-Noir, of which the latter is the favourite. It is very seldom that large sums are staked at the former, as the chances against the player are considered immense by *professional* men, a class of gentlemen who are gamblers by profession. Rouge-et-Noir is played with four packs of cards, and the "couleur" which is nearest 31 wins; the black being dealt for first, and then the red. All the houses were open from one o'clock in the afternoon till one or two after midnight; and latterly till five or six in the morning. The highest play, especially at Frascati's, was carried on between three and six in the afternoon. Ten or twelve thousand francs were constantly lost at a sitting, and once 100,000 francs, which constituted the "Banque" of the day, was won by a French nobleman. The actual chance of the table or "Banque" is considered to be 7½ per cent. above that of the player, supposing the game to be fairly played, as it no doubt was in Paris under the old system; the cards being examined and stamped by the government, and there being an agent of the police always present and ready to detect any attempted fraud on the part of the company. But admitting the game to be fairly played, the coolness of the "croupiers" or dealers, who had no interest at stake—the whole of the losses or gains being taken by the company,—and the large capital of the latter, made it absolutely impossible for the player to win in the long run; nay, it is clear that he must lose, and that in proportion to his stake, which probably is regulated by his means. This we have heard admitted by the most constant frequenters of these houses; and nevertheless, under the influence of those causes which first lead men to gaming, confirmed by habit and example, they still continue to indulge their passion till they are reduced to beggary, which is often followed by suicide.

That a vice which causes so much wretchedness should not merely be permitted and the practice of it superintended by the government, but that it should contribute considerably to the public revenue, was a subject of loud complaint in France; and at last the ministers, in compliance with the desire of the Chamber of Deputies, determined to grant no more licences after the 1st of January, 1838.

In most parts of Germany gaming is allowed; and the magnificent saloons set apart for roulette and rouge-et-noir at Baden, Wiesbaden, and other German watering-places, are well known to English travellers on the Continent. The respective sovereigns of the states in which these fashionable gaming-places exist derive an immense revenue by letting the exclusive privilege of keeping gaming establishments; and we may frequently see the grand duke or prince playing at the table of his lessee, and losing a considerable portion of what he receives for granting the privilege.

In Italy and Spain gambling is a very common vice, especially among the lower orders, and you scarcely can find a muleteer, porter, or shoe-black, who has not a pack of dirty cards in his pocket, which he pulls out whenever he has a moment's leisure; and should he not be lucky enough to find a partner who will risk his money against him, he will frequently give a boy a trifle to play with him.

In the United States of America, but more particularly in the Southern States, the practice of gambling is very common, though restrained, as we believe, in all the States by legislative enactments.

The following abstracts of the laws relating to gaming in different countries were prepared by J. M. Ludlow, Esq., and were laid before the Select Committee of the House of Commons on gaming, by H. Bellenden Ker, Esq.:—

By the French law, as it stood before the Revolution, minors alone could recover their losses at play; but no winnings could be sued for except in the case of warlike sports; when not excessive, games of strength and skill were permitted, games of mere chance absolutely forbidden.

The Code Français allows an action for money won at games of strength and skill, when the amount is not excessive; but money paid can never be recovered, unless on the ground of fraud. The keepers of gaming-houses, their managers or agents, are punishable with fine (100 to 6000 francs), and imprisonment (two to six months), and may be deprived of most of their civil rights. A trifling fine is imposed on those who set up lotteries, or games of chance in public places; the furniture, implements, &c. are in all cases to be seized.

By the Prussian Code all games of chance, except when licensed by the state, are prohibited. Gaming debts are not the subject of action; but money paid cannot be sued for by the loser. Wagers give a right of action when the stakes are constituted in cash in the hands of a third person; they are void when the winner had a knowledge of the event, and concealed it. Money lent for gambling or betting purposes, or to pay gambling or betting debts, cannot be sued for. Gaming-house keepers are punishable with fine, professed gamblers with banishment; and if they break the ban, by imprisonment. Occasional cheating at play obliges to compensation; professed swindlers at play are punishable as for theft, and banished afterwards. Money won from a drunken man, if to a considerable amount, must be returned, and a fine paid of equal value.

In Austria no right of action is given either to winner or loser. All games of chance are prohibited, except when licensed by the state. Cheating at play is punishable with imprisonment, according to the amount of fraudulent gain. Playing at unlawful games, or allowing such to take place in one's house, subjects the party to a heavy fine, or in default to imprisonment.

The provisions of the Sardinian civil code are similar to those of the French, giving an action for money won at games of strength or skill, when not excessive in amount; but not allowing the recovery of money lost, except on the ground of fraud or minority (a provision taken from the old French law).

The Bavarian code is somewhat special in its provisions; it distinguishes between games of pure skill, and mixed skill and chance on the one hand, and games of mere chance on the other. In the two former, money honestly won, and not excessive in amount, may be lawfully claimed, and money lost cannot be recovered; but with respect to fraudulent or excessive gaming, and also as to all games of mere chance, the winner may be called upon to repay his gains, and is liable, together with the loser (except as to the latter, in the case of fraud), to a penalty of varying amount. Gaming-house keepers and professed gamblers are subjected to various penalties. Distinctions are also taken as to wagers, which are only void for fraud or immorality, but the amount of which is liable to be reduced, if excessive. When money lost at play is proved to have been the property of some other person than the player, the true owner may recover it.

Wagers also appear to be lawful in Spain, when not in themselves fraudulent or relating to anything unlawful or immoral. (Johnson's 'Institutes of the Civil Law of Spain,' p. 242.)

GAMMUT, in Music, signifies, in the popular sense of the word, the *diatonic scale*, as named either by the seven first letters of the alphabet, or by the syllables used in solmisation, that is, *do*, *re*, *mi*, *fa*, *sol*, *la*, *si*. [DIATONIC SCALE.] And occasionally the term is applied to a single note—the G below the base clef. The word is compounded of the name of the third letter in the Greek alphabet, Γ (gamma), the final vowel being cut off, with the syllable *ut* added. In the 11th century the ancient scale was extended by the addition of a note below that sound which the Greeks called *proslambanomenos* (that is, supernumerary), the latter answering to our A, the first space of the base staff, and the note was called *Gamm'-ut*,—that is, G *ut*, or G *do*.

The invention of the gammut in its antiquated form is generally ascribed to Guido d'Arezzo, but it now seems nearly certain that in part, if not wholly, it existed much earlier than his period. It long continued in use, and was one of the many stumbling-blocks in the path of musical students. Happily little more than the name remains; it is therefore unnecessary for us to enter further into the subject.

GAOL. [PRISON; PENAL SERVITUDE.]

GAOL DELIVERY. The commission of gaol delivery is directed to the justices of assize of each circuit, the serjeants and queen's counsel attending that circuit, the clerk of the assize, and the judges' associate. It is a patent in the nature of a letter from the sovereign, constituting them his justices, and commanding them, four, three, or two of them, (of which number there must be *one* at least of the judges and others specified) to deliver his gaol at a particular town of the prisoners in it; it also informs them that the sheriff is commanded to bring the prisoners and their attachments before them at a day to be named by the commissioners themselves. Under this commission the judges may proceed upon any indictment of felony or trespass found before other justices against any person in the prison mentioned in their commission and not determined, in which respect their authority differs from that of justices of oyer and terminer, who can proceed only upon indictment found before themselves. (2 Hale, P. C.) [ASSIZE.]

Anciently it was the course to issue special writs of gaol delivery for each prisoner, but this being found inconvenient and oppressive, a general commission has long been established in their stead. (4 Bl. 'Com.;' Hawk, P. C.)

GARANCIN. [MADDER, *colouring matters of.*]

GARDEN. A garden, as distinguished from a farm, is a piece of ground designed for the cultivation of plants not actually indispensable to man for food. While corn for flour, various roots and herbs for the sustenance of cattle, or tracts of pasture land on which animals destined for slaughter are maintained, constitute the essential features of a farm; a garden, even when exclusively occupied by culinary vegetables, is still a source of objects of luxury, not of first necessity. In a more extended sense, and as it usually exists at the present day, it is chiefly intended to gratify the senses and to minister to the more refined enjoyments of social life.

The possession of a garden is one of the most early indications of civilisation in man, and it is only among the most brutal and degraded races of savages that it is altogether unknown; while we find such an appendage to a dwelling increased in magnificence, or diminished and neglected, with the prosperity or decline of the most mighty states. It is Lord Bacon who says that "when ages do grow to civility and elegancy, men come to build stately sooner than to garden finely, as if gardening were the greater perfection."

According to Sir John Malcolm, the Persians had gardens from the period of their first king Mahabad. We learn from Xenophon that Cyrus considered them an indispensable appendage of his residences. "Wherever he resides, or whatever place he visits in his dominions, he takes care that the *paradises* shall be filled with all that is beautiful and useful which the soil can produce." ('Cyropæd.' v.) And it appears upon the testimony of Pliny and other Roman authors, that among the same people small gardens existed, in which trees were arranged in straight lines and regular figures, the margins of the walks being planted with tufts of roses, violets, and other odoriferous flowering plants, while the trees consisted of kinds grateful for their fragrance, as the cypress and the pine, or agreeable for their shade, as the plane and the common elm. The Greeks, in their most flourishing times, appear to have been equally attached to the formation of gardens, and even, in some respects, to the nicer parts of the art of gardening. The Oriental narcissus, violet, ivy, and rose, are mentioned as their favourite flowers, and terebinthinous trees as those which were chiefly valued for their fragrance. The rich and polished Athenians are represented by Mr. Meason as having borrowed their gardening from Asia Minor. Myrtles and roses, the box and the lime-tree, were planted for clipping into artificial forms, while flowers and fruits were cultivated in the winter, and the violet was in profusion in the Athenian markets when snow was lying on the ground.

Theophrastus himself not only gives directions for gardening operations, many of which were fanciful enough, such as sowing rue with chips of fig-wood, and pulling up esculents by way of making them more tender, instead of cutting them; but he had a garden of his own which he left to ten of his friends to be preserved as a place of public resort for those who employed their leisure in letters and philosophy. (Diogen. Laert., v. 53.) The instances of the kings Attalus Philometor [ATTALUS, in BIOG. DIV.] and Mithridates, who cultivated all sorts of poisonous plants in their gardens, are perhaps the earliest upon record of such places being occupied for medical purposes.

It is not to be supposed that gardens were neglected by the luxurious and wealthy Romans. The prodigious gardens of Lucullus, who introduced the cherry, the peach, and the apricot from the Persians, were derided by his Roman friends for their extraordinary sumptuosity. They are related to have consisted of immense artificial towers, large sheets of water, gigantic edifices jutting into the sea, and mountains raised where no hill had existed before. Such an example might be ridiculed by some, but was certain to be followed by others whose taste for splendour and profusion was supported by unbounded wealth; and, accordingly, the gardens of Sallust, of the emperors Nero and Hadrian, and of many of their subjects, are doubtless to be classed in the same order as those of Lucullus. It is, however, to be remembered, that such gardens were rather more similar to an English park and garden combined than to a mere garden, in the modern sense of the word, and moreover were so uncommon as to be looked upon with wonder by the people among whom they were created. A common Roman garden must have been a very different place, if we are to take the description given by Virgil ('Georgic.,' iv. 121) as at all a faithful sketch; for he speaks of nothing but endive (intyba), celery (apium), melons? (cucumis), narcissi, acanthus, roses, ivy, and myrtles. That they had various trees bearing fruit, as well as the common wild timber of the country, and many different kinds of flowers, must of course be admitted; but that all gardens, up to the most flourishing period of the Roman empire, must have been much alike as regards the plants they contained, is manifest from the fact that hardly more than seventy plants of all descriptions are noticed by this poet, although he wrote professedly upon rural affairs. It is true that the Romans carried their passion for flowers so far that it became necessary to restrain it by sumptuary laws, and that cases of extreme profusion in the use of them are mentioned by historians. The institution of Floralia, or flower-feasts, the universal passion for garlands, the reproaches addressed by Cicero to Verres for having made the tour of Sicily in a litter, seated on roses and decked with festoons of flowers, are a sufficient evidence of this taste having been carried to an extent unknown at the present day; to say nothing of the prodigality of Heliogabalus, or of Cleopatra, the latter of whom is said by Athenæus to have paid upwards of 200*l.* (an Egyptian talent) for roses expended at one supper. But notwithstanding this, the variety of plants that were cultivated in the gardens of both Greeks and Romans must have been extremely small. Theophrastus speaks only of roses, gillyflowers, violets, narcissi, and iris, as used for decoration, to which the larkspur and gladiolus (hyacinthus), with the white lily, and a few others, may be added. The great object of their admiration was roses, which were forced by plates of talc (said to have been as much as five feet long; but it is more probable that these *specularia* were sashes five feet long, glazed with talc) being placed over bushes watered with warm water. Pliny, in his 'Natural History,' does not enumerate above 1000 plants of all descriptions,—a very small part of which were objects of cultivation. At the fall of the Roman empire the following appear, from Mr. Loudon's statement, to have been the principal garden plants, exclusive of common trees and flowers. 1. *Culinary plants:*—peas, beans, vetches, lentils, kidney-beans, gourds, cucumbers, melons, cabbages of many sorts, turnips, carrots, parsnips, beet, skirret, radishes, sorrel, asparagus, onion, garlic, and other alliaceous plants, endive, lettuce, succory, mustard, and other salads, parsley, celery, orach, alexanders, elecampane, fennel, chervil, and some others. 2. *Fruits:*—fig, almond, citron, peach, pomegranate, apricot, plums, and cherries; twenty-two sorts of apples, thirty-six sorts of pears, services, quinces, and medlars; many kind of grapes, mulberries, nuts, walnuts, chesnuts, stone-pines, or pignons, olives, and carobs. They forced flowers with sashes of talc, as has already been noticed, and also cucumbers; it is probable that they extended this practice even to fruits.

With the fall of the Roman empire the art of gardening seems to have been lost, and it was not till a long time after that gardens are again heard of. It was among the monks that the arts of cultivation were preserved, and in connection with monastic institutions gardens again became matter of history. In these religious institutions, which were in many respects the only spots where the arts of peace could find shelter during ages of rapine and violence, gardens continued to be cherished; and although the ignorance of the monks prevented their being rendered so useful as they might have been, yet, on the other hand, their sacred protection opposed an effectual barrier to the wild progress of destruction.

Among his many reformations, the re-establishment of gardens formed part of the policy of the emperor Charlemagne, who introduced the subject into his *capitularies*, commanding gardens to be formed throughout his dominions, and prescribing the very plants which were to be cultivated therein: and considering the state of learning in those days, it must be admitted that the list, short as it is, was prepared with good judgment; for it was made to contain the most useful plants then known for diet or medicine, as well as the favourite ornamental flowers of the Romans. The reader of the present day may be amused at the list of what was thought in the 8th century deserving of an imperial edict, at a time when no one had heard of a garden except within the walls of a castle or a monastery (*Walafridi Strabi Hortulus*):—Roses, lilies, fenugreek, costmary (*Costus*), sage, rue, southernwood, melons, gourds (*Cucurbitæ*), water melons (*Pepones*), kidney beans, cummin, rosemary, caroway, lentils, squills (?), gladiolus, tarragon, cucumbers (*Coloquintida*), heliotrope, (*Ammi majus*, *Sium angustifolium*), lettuce, nigella sativa, rocket (*Eruca*), nasturtium, dock, alexanders, parsley, celery, savin, fennel, dittany, woodmint, watermint, catmint, centaury, beet, marsh mallows, carrot, orach (*Adripia*), kohl rabi, chives, radishes, onions, madder, beans, chervil, clary, lovage, anise, succory, mustard, savory, mint, tansy, poppy, asarabacca, hollyhocks, parsnip, blite, cabbage, leeks, rocambole, garlic, teasel, peas, euphorbia lathyris (*Lacterula*), houseleek. From this proceeding of Charlemagne the revival of gardens may be said to date, for although there are few direct traces of their existence for some centuries, yet there is no reason whatever to suppose that they were ever again lost sight of. In the 14th century we find Matthæus Sylvaticus, a Mantuan physician, speaking of his own garden, and of a Colocasia cultivated in his greenhouse on the edge of a beautiful fountain, and of a plant called Cantalis, supposed to be Athamanta cretensis, which he says he brought out of Greece and planted in his garden. ('Pandect.,' c. 197, 133.) It was however in Italy that the formation of gardens received a fresh impulse. Alfonso d'Este, duke of Ferrara, is recorded to have founded several botanic gardens in the 16th century, and especially one called Belvedere, surrounded by the water of the Po. The example was followed by several nobles of Ferrara; John Brasavolo, the uncle of the botanist Musa Brasavolo, had a viridarium or greenhouse; another noble, of the name of Acciajuoli, had many rare plants in his garden; and the collections of this city, augmented annually by the commerce of its merchants with Greece and Asia, became so rich in new exotic plants as to become celebrated all over Europe. The Ferrara gardens were soon rivalled by those of the Venetians and Paduans, one of whom, Gaspard de Gabrichis, is said to have spared no expense to enrich his garden, not with costly edifices and vast architectural embellishments, but with plants before unknown. (Spreng. 'de R. H.' iv. c. 3.) The greatest and earliest garden however of this era is generally considered to have been that founded at Pisa, in 1544, by Cosmo de' Medici, on the banks of the Arno; which by the year 1555 had become so rich in plants by the exertions of Lucas Ghini and his successor Cæsalpinus, as to have been the admiration of Belon, no mean judge. Haller indeed is of opinion that a greenhouse built by the bishop of Acquapendente dates from the year 1533, but this is at variance with the statement of Tiraboschi, who fixes the erection in the year 1545. Be this as it may, it is at least certain that about this period a public garden was formed at Bologna, others at Lucca, Naples, and Florence; and that at Verona one Cæsar Niclesola had two large greenhouses in which some very rare plants were preserved. (Pona, 'It. Bald.' p. 9.)

At this time Paris possessed no garden for its university; that of Montpellier had, however, been founded by Henri IV., and contained before the end of the 16th century upwards of 1300 French, Alpine, and Pyrenean plants, according to Olivier de Sevres ('Traité d'Agricult.,' 1600), and a famous garden had been created at Mans by Renate Bellaye, bishop of that city. In Germany too, the garden of Breslau, to which Tragus and Fuchs were attached, of Basel, Strasburg, and other places, were at this time in existence, and the since celebrated garden at Leyden had been founded in 1577, at the instance of Gerard Bontius.

The principal part of these establishments were founded for academical purposes; when they were formed for private gratification their owners must be considered very much in advance of their times, if we are to form an opinion from the state of private gardening in this country at the same period. Here the only purpose contemplated in the formation of a garden appears to have been an enclosed place in which the owner might walk in seclusion, or in which sport might be had with contrivances like mazes and labyrinths formed of close-cut hedges; a few fruit-trees were added; but no such object as that entertained by the refined Italians, of collecting rare and beautiful plants from foreign countries for pleasure or for scientific purposes, was thought of. In the gardens of Nonesuch, the palace of Henry VIII., executed about the year 1540, we hear of shady walks, columns and pyramids of marble, "fountains that spout water one round the other like a pyramid, upon which are perched small birds that stream water out of their bills," and of similar objects, but nothing of the more essential part of a garden—its plants. Pleasure-grounds of this description had existed in England from the time of the Conqueror. It is stated by Fitzstephen that in the time of Henry II. (1154—1189) the citizens of London had large and beautiful gardens to their villas. In the reign of Edward I. (1272—1307) it may be collected from 'Holinshed's Chronicle,' that the cultivation of the garden was extended to the more curious and delicate productions; but the wars of York and Lancaster destroyed all these occupations, and gardens in general ceased to be more than pleasure-grounds or kitchen-gardens of the rudest kind till the time of Elizabeth. King James I. of Scotland describes the garden at Windsor Castle, where he was confined by Henry V., as a place set thick with trees, and alleys of hawthorn hedges, with an arbour in each corner,—

> "And myddis every herbore might be sene
> The scharp green swete jenepere."—*The Quair.*

Much later (1512) the great Earl of Northumberland, whose household consisted of 160 persons, had but one gardener, who attended hourly in the garden "for setting of erbis and clipping of knottis, and sweeping the said garden clean." Nay, it should seem as if sometimes there was not even one; for among the workmen of the household is mentioned the gardener of the place where my lord lyeth, *if there be one.* (Loudon.)

In these remarks all reference is omitted to the gardens of the Arabs; about which almost nothing is known, but which seem to have been more deserving historical record than those of other contemporary nations. That this people in the height of their power paid great attention to botany, is well known to those who are familiar with that science. A learned work on rural affairs was written in the 12th century by Abu Zachariah Ebn Alva, a native of Seville, of which an epitome has been given by Casirius ('Bibl. Escurial,' i. 326, s.); and according to Mr. Loudon, this writer has left a list of plants cultivated in the garden of Seville, more extensive than that of the Greeks and Romans. In the 13th century the then Vizir of Cairo, Ebn-Beitar, a native of Malaga, was so much attached to botany that he visited all parts of the East for the express purpose of extending his knowledge of plants. His works are preserved in MSS. in the library of the Escurial, and it is said that although he scrupulously abstained from describing anything which he had not seen, yet he speaks of 2000 species more than Dioscorides. (Spreng., i. 238.) It is only reasonable to suppose that such a man had a garden. We must, however, fix the period when gardens first began to be extensively improved, in the middle of the 16th century, when, as has been already shown, the rich Italians turned their attention to the introduction of new and rare plants. By the time that this new taste began to be fixed in the minds of Europeans, the numerous geographical discoveries that had been made by the Portuguese and Spaniards, had opened new and unheard-of sources from which the lovers of gardens were able to enrich them. It would appear that the maize, the yam, tobacco, and the cotton-tree (*Bombax*) were brought to Europe by the Spaniards so early as the end of the 15th century (Barcia, 'Hist.' i. 24), and King Ferdinand is recorded to have preferred the pine-apple, brought home in Columbus's second voyage, to all other fruits. (Petr. Martyr. 'Reb. Oc. Dec.' l. 2, b. 39.)

It would be impossible to trace the progress of public taste in the construction of gardens any farther historically, without occupying more space than such a subject can have allotted to it in a work of this description. It may easily be conceived that from the time when the taste for gardens revived, up to the present period, there has been a gradual improvement in such places, commensurate with the wealth of individuals and the commercial power of nations, their peaceful habits, the security of property, and their general progress in settling the relations of social life. In the remainder of this article we shall offer a few remarks upon the most important causes which have contributed to bring gardens to their present improved condition, and conclude by a brief account of some of the most remarkable Botanical Gardens of the present day.

The first great step that was made by gardeners to advance their art beyond mere mechanical operations, was the invention of glasshouses, in which plants might be grown in an artificial climate, and protected from the inclemency of the weather. Until this was effected, it is obvious that the cultivation of exotic plants in Europe, especially its northern kingdoms, must have been much circumscribed. Mr. Loudon refers the invention of greenhouses to Solomon de Caus, architect and engineer to the Elector Palatine, and who constructed the gardens at Heidelberg in 1619. But there can be no doubt that buildings of this description claim a higher antiquity. The specularia of the Romans, whether pieces of talc 5 feet long, or, as we rather suppose, sashes 5 feet long glazed with talc, were certainly used for the purpose of forcing roses and some other plants; they were essentially greenhouses, although perhaps more like our garden-frames. It is scarcely likely that where gardening survived, the learned men, in whose hands all such subjects then were, should have been unacquainted with the existence of these specularia, and they would naturally endeavour to reconstruct them. Greenhouses certainly existed among the Italians in the middle of the 16th century, as has been already mentioned, and there is no reason to suppose they had then for the first time been thought of. In fact, the ancient viridarium seems to have been a room with one side of it glazed with sashes reaching from the top to the bottom, and resembling the old English conservatory. It may or may not have been heated; probably not, for it was chiefly Greek, Egyptian, and Levant plants that were at first cultivated as rarities by the wealthy Italians, and they required no artificial heat in Italy.

If heat were required, it would be supplied by stoves or such other contrivances as were used for domestic purposes. Ray says, that in 1684 the greenhouse in the Apothecaries' garden at Chelsea was heated by means of embers placed in a hole in the floor: and it appears, from a section of a greenhouse in the Electoral garden at Manheim, published in 'Medicus Index Plantarum,' that a German stove was used there as late as 1771. We however agree with Mr. Loudon in considering the invention of *glass-roofs* for greenhouses to be an æra from which the principal part of modern improvements takes its date. This happened in 1717, when Switzer published the plan of a forcing-house, suggested by the Duke of Rutland's graperies at Belvoir Castle. Up to that time the want of light must have rendered it impossible to employ greenhouses for the growth of plants, either in winter or summer; they could only have been hybernatories, receptacles in which plants might be protected from wet or cold during winter, but from which they were transferred to the open air as soon as the spring became sufficiently mild. The substitution of glass-roofs, by increasing the quantity of light, put it at once in the power of the gardener to cultivate permanently in his greenhouse those natives of hot countries which are not capable of bearing the open air of Europe even during the summer. From the time of Switzer to the present day there has been a gradual improvement in the construction of greenhouses, the object being to supply the plants with as nearly the same amount of light when under the glass-roof, as they would have had if in the open air. The modern invention of curvilinear iron-roofs has accomplished this end in a most remarkable degree; for they substitute an obstruction to light amounting to only $\frac{1}{18}$ or $\frac{1}{17}$ for a loss equivalent to $\frac{1}{4}$ or even $\frac{1}{3}$.

The mode of heating such houses has given the modern cultivator additional advantages of the greatest importance. Stoves of all kinds not only dry up the moisture of the atmosphere, but impregnate the air with gaseous exhalations unfavourable to vegetation. The substitution of flues, while it equalised the heat, was still worse than the stove in drying and deteriorating the air; the introduction of fermenting vegetable matter, such as tan in a pit, in the interior of the house, remedied this evil in some measure, but the application of steam-pipes or hot-water pipes has had the great advantage of obviating every inconvenience, and has given the gardener the power of modifying the heat and moisture of his greenhouse at pleasure. Add to this, the rapidity of communication between one country and another, the long peace with which Europe was blessed, and the leisure it gave men to occupy themselves with domestic enjoyments, the great encouragement given to gardeners, the establishment of Horticultural Societies for the promotion of the art of gardening, and the discoveries made in vegetable physiology—add all these things to the improvements in greenhouses, under which name is here included all descriptions of glass buildings for horticultural purposes, and there is no difficulty in accounting for the present flourishing condition of European gardens.

There is one point further that requires to be noticed, as contributing to this result, and that is, the extension of the education of the working gardener. Great numbers of gardeners are now well informed in the higher branches of their profession. Instead of trusting to certain empirical rules, or to *receipts* for gardening operations, as if growing a plant was much the same thing as making a pudding, they make themselves acquainted with the principles upon which their operations are conducted; they acquire a knowledge of botany and vegetable physiology, and some even of physical geography, and thus they place themselves in the only position from which they can securely advance to the improvement of their art. The necessity of these subjects forming a part of all gardeners' education cannot be too strongly insisted upon; the Horticultural Society of London have recognised their importance by requiring all the young men in their garden to pass an examination in such subjects, in addition to their possessing the usual gardeners' acquirements; and although people ignorant of such subjects themselves have been found absurd enough to blame the proceeding, there can be no doubt that the world will give the Society the credit they deserve for having been the first to set this most important example, which we trust will be followed by all such institutions through the country.

In noticing modern gardens we must necessarily confine ourselves to a few of the most remarkable, passing by entirely those of private individuals, and in general all second-rate public establishments. The reader who is desirous of procuring detailed information upon the subject will find an ample account of all the best modern gardens in Mr. Loudon's excellent 'Encyclopedia of Gardening,' to which we have been much indebted for this article.

Although the restoration of gardens took place among the nobles of Italy, and many noble instances of wealth and taste applied to such purposes still remain, yet the political condition of that country is unfavourable to horticultural pursuits, and although there are gardens attached to most of the Italian cities, there are none of much note, except for their picturesque features and fine architectural embellishments. Those of Naples, Florence, and Monza near Milan, are among the most remarkable.

The Dutch, although too much attached to the stiff formal style of clipped hedges, straight walks, and architectural puerilities, have always had a great reputation as gardeners. Their wealth and their commerce with the Cape of Good Hope and the East Indies gave them for a while extraordinary advantages over other nations, and for a long time their garden of Leyden was considered the richest in Europe. It was begun in 1577; in 1633 it contained 1104 species, and was so rapidly enriched by the zeal of the wealthy Dutch merchants, that in 1720 no fewer than 6000 species were catalogued by Boerhaave, who was then professor of botany at Leyden. From this source was at one time obtained the principal part of the succulent and other plants native of the Cape of Good Hope. It was afterwards a good deal neglected, but was renovated under the care of Dr. Blume, and now ranks again among the finest of the public gardens of Europe.

In the Netherlands there are small public gardens, both at Antwerp and Ghent, and one of the finest in Europe at Brussels. Some years since it was a wretched place, scarcely deserving the name of a garden; but in 1826 it was removed to its present site on the boulevards, and entirely re-formed. It now contains extensive ranges of hothouses, and a large collection of plants. The roof of the houses is formed of curvilinear iron bars, and the whole is heated by steam. The principal range is seated on a terrace, with several fountains and broad flights of steps in front of it; while on a lower level are low ranges of pits for pine-apple plants and small tropical species.

Among the German sovereigns a taste for gardening has grown up in a degree unknown in any other country except among the English. A love of the beautiful, a fondness for natural objects, a quiet contented character, so characteristic of the German nations, has no doubt been the cause of this. In Loudon's 'History of Gardening,' no fewer than ninety closely printed pages are occupied with short accounts of the principal gardens of Germany only. Of these we can only select those of Munich, Berlin, and Vienna.

The garden of Munich is extremely rich in plants that can be cultivated in greenhouses and hothouses, but poor in those species which require to be grown in the open air: this happens in consequence of the severity of the winter, which destroys even the holly. There is a very fine range of hothouses, containing numerous palms, succulent and other plants. It is however considered that the plants, especially the Brazilian plants, in the hothouses at Nymphenburg are much finer than those at Munich.

The botanic garden at Berlin has long been one of the great sources from which the gardens of Europe have derived supplies of new plants, chiefly from Brazil, Mexico, and the Cape of Good Hope, in which country the king of Prussia has maintained collectors. It contains many hothouses and greenhouses, each of which is often dedicated to the reception of plants of some one tribe only. There is one for endogenous plants exclusively, another for ferns and palms, a third for Australian plants, and others for heaths, Cape, and Mexican plants; there are some very fine palms, and in all respects the collection of species is one of the most extensive in the world.

If the garden of Schönbrunn is less rich in plants than that of Berlin, it much excels it in the magnificence of its hothouses and greenhouses. The emperors of Austria have for above a century been anxious to render this garden the finest in the world; and no cost has been spared in sending gardeners to foreign countries in order to increase the collection. It is however chiefly by supplies from the tropical parts of America that this garden has been enriched. There are several ranges of glasshouses, in which the species are grouped with great taste, and which from their size allow the plants to grow with all their native tropical luxuriance.

Rivalling these imperial structures are the gardens of St. Petersburg, founded by the emperor Alexander on the Apothecaries' Island in the Neva. In a country with such a climate as Russia gardening can hardly exist, except with artificial heat under glass roofs, and it is necessary to call in aid all the resources of art in order to overcome the difficulties of nature. It is not surprising then that in this situation the glasshouses should exceed in extent those of all other parts of Europe. In the open ground there is a large collection of hardy plants, a quarter devoted to systematical botany for the purposes of students, an arboretum, and a division for medicinal species. One excellent feature in the internal arrangements of this garden is the placing the plants geographically, so that the most careless observer in proceeding through the different suites cannot fail to be struck with the changes in vegetation as he passes from Africa to America, to Australia, to India, China, and so on.

In France gardening has never been in a very flourishing condition; it is true that great quantities of vegetables are raised for the market, that the fruits of France are justly celebrated for their excellence, and the flower-markets of Paris are well supplied; it is also true that numerous excellent works on gardening have been written in France. But for the quality of their fruit the French are chiefly indebted to their climate, for the abundant supply of the vegetable market to their peculiar cookery, and for the excellence of their written works rather to the ingenuity of a few clever men, than to the general habits of the community. In flowers their taste is rather that of the Romans than of other European nations, for they are contented with a few showy kinds of sweet-smelling flowers, especially roses. Their great public gardens rather resemble in character those of the days of Henry VIII., than of the 19th century. There no doubt are exceptions to this statement, but the Jardin des Plantes at Paris, which is the largest of the public establishments in France to which the name of garden properly applies, is scarcely one. For a considerable period it consisted merely of various departments, in the open air, devoted to purposes of teaching; of an indifferent collection of hardy herbaceous plants, and hardy trees and shrubs; and of some contrivances to aid the student of agriculture. Of late years large glass-houses have been built, and many improvements made, yet even now there are few judges of gardens who would assign the Jardin des Plantes a place among the first class of European gardens.

In Great Britain it has not been the policy of the government to offer direct encouragement to either science or art, except in a sparing manner, but rather to throw the duty of fostering them upon the people. So far as gardening is concerned the government has been right; for if in this country such public gardens as we have enumerated are unknown, on the other hand no part of the Continent possesses such multitudes of good private gardens as Great

Britain. That which in other countries is a luxury, provided for at the public expense, is here rendered a kind of necessity, which all persons, from the cottager to the noble, strive to possess. Nothing can be more beneficial to the community, or more advantageous to horticulture itself, than this difference, for the result is not here and there a magnificent garden, and all around it comparative sterility, but a universal garden all over the country. The chief English garden containing a large collection of plants is that of Kew, which is certainly the richest in the world in Australian, New Zealand, and Himalayan plants, and which was, during the war following the first French revolution, almost the only place in Europe to which exotic plants were introduced in considerable quantity. In consequence of this establishment having had a monopoly of government support for above fifty years, it has been the channel through which an enormous quantity of new plants have been introduced to Europe from all parts of the world. For many years however it was unworthy of the nation, from the illiberal manner in which it was conducted. Of late years this system has been abandoned, a liberal management has been introduced, the collection is at least as accessible as that of other nations, and under the enlightened direction of Sir W. J. Hooker, the whole establishment has assumed such a magnitude and importance as to place it far above all other institutions of the kind. It now embraces within the botanic garden proper an area of seventy-five acres; has a noble palm house, 362 feet long, and in the centre 100 feet wide, and 66 feet high; several good hothouses; a new museum, &c.

Next in importance among public gardens was that of the Horticultural Society, at Chiswick, near London. It had been established at the expense of the members of the society, and was intended both as a place of experimental researches in horticultural science, and as a station whence the most valuable, useful, and ornamental plants of all kinds, might be distributed through the country; for which purposes its extent, amounting to 33 acres, was expected to be amply sufficient. For more than 30 years it exercised a most important influence over the progress of horticulture, and was the medium of introducing by far the greater part of the valuable exotics which have found their way into cultivation since its foundation. No association of individuals ever produced so marked an effect upon gardening in a few years as was brought about by the enormous distributions of cuttings of improved fruit-trees, of the finest kinds of vegetable seeds, and of new plants mostly imported direct from the British colonies and from the west coast of America, made annually from this garden, independently of the collections sent in return to all parts of the world. Of late years, however, it has been merely maintained as a place of experiment, and is about to be replaced by a new garden at Kensington Gore, at a cost of 100,000*l.*

A very successful establishment of a nearly similar kind is the Royal Society's Botanic Garden, which occupies the inner circle (an area of eighteen acres), in the Regent's Park. It has a very spacious conservatory, greenhouses, and an excellent collection of plants.

The botanic garden of Edinburgh is one of the finest and best-managed in Europe. It consists of 16 acres, delightfully situated, and includes everything that can be required for the purposes of teaching. The houses are remarkably good, and the healthy condition of the plants deserving of all praise. It is particularly celebrated for its beautiful specimens of heaths. Besides these, there are botanic gardens at Dublin, Glasgow, Liverpool, Cambridge, and Oxford; fine public gardens in Sheffield, Manchester, Birmingham, and some other large towns; and a garden at Chelsea, belonging to the Apothecaries' Company, who maintain it for the use of the medical students of the London schools. The Chelsea garden was once among the most celebrated in Europe, having been for nearly fifty years under the management of Philip Miller, the author of the 'Gardeners' Dictionary,' and whom Linnæus called the "prince of gardeners." Its situation has however become unfavourable for a garden, in consequence of the number of houses with which it is surrounded.

The number of species included in Loudon's 'Hortus Britannicus,' or catalogue of the plants either cultivated in Great Britain or indigenous, amounted in 1830 to upwards of 25,000, exclusive of Cryptogamous plants; and although a vast number of deductions must be made, it is not improbable that there are at this time nearly as many species known in the different British collections.

GARDEN HUSBANDRY is a branch of horticulture, the object of which is to raise fruits, vegetables, and seeds for profit on a smaller extent of ground than is usually occupied for the purpose of agriculture.

The best examples of this kind of industry are found among the market-gardeners near populous towns, particularly London, Paris, and Amsterdam. By the application of much manual labour and an abundant supply of manure they accelerate the growth of vegetables, and produce them more abundantly than where manure is not so easily obtained, or where there is not so large a demand for the produce.

The gardeners near Paris, some of whom have gardens within the outer walls of the city, are called *Maraichers*, from the situation of their gardens in a low district which was formerly a marsh (*marais*). The industry of this laborious class is proverbial. Their whole life is devoted to their gardens. They work the whole day in the greatest heat of the sun, and long before the rest of the inhabitants awake they are on their way to the market with their produce. The soil in which they raise their vegetables is naturally a poor sand, but by constant manuring it has been converted into a very rich mould abounding in humus. From its porous nature, and the frequent recurrence of dry summers, it would produce little without constant and abundant watering. The raising of water from numerous wells dispersed through the grounds, and conveying it to the growing plants, is the most laborious part of the work: during the whole summer this labour is incessant. There are large stone cisterns in which the water is allowed to remain, that it may acquire the temperature of the air; and from these it is carried by pipes into various channels which intersect the garden in every direction. These gardeners divide the season into three periods. The first begins in October, when they sow lettuces in a hot-bed, which are pricked out a month after, and planted finally in a sheltered border about the end of January, the ground having been well dug and abundantly manured with very rotten dung taken from the hotbeds. At the same time they sow radishes and leeks among the lettuces. The radishes are sold by the end of March, the lettuces in May, and the leeks in June. This completes the first season. The ground is now dug again, and manured with fresh long stable dung mixed with the earth of which the hotbeds were formed; in this they plant alternate rows of endive or scarolles (both varieties of chicory), and of cucumbers, which produce gherkins for pickling and sauces. The endive is sold in July, and the small cucumbers continue to be gathered till September. In the third season, which is the shortest, another digging and dunging is given, after which they sow radishes and small winter-salad, of which the French have a great variety. Winter endive is also planted for blanching. From this statement it appears that the ground produces a constant succession of culinary vegetables, and that it is manured thrice in the year. The great object is to have a rapid succession, and to allow no plant to occupy the ground long. Cabbages, cauliflowers, asparagus, artichokes, and other vegetables which remain a long time on the ground, are cultivated at a greater distance from Paris, where the land lets at a lower rate. These plants will bear to be carried to a greater distance than the delicate vegetables which are used chiefly in a raw state as salads. The only perennial plant in the gardens of the Maraichers is sorrel, of which there is a great consumption. This is continually dunged and watered to accelerate its growth, and is cut many times in the season. It must however be allowed that this forcing with manure and water, although it produces large and delicate fibres, does not give the flavour which belongs to vegetables grown in common earth, and which have had a more natural growth.

The market-gardens near London are on a larger scale, and if they produce fewer salads and pot-herbs, they produce better and more substantial vegetables, and likewise a large quantity of fruit. The best soil is a moist alluvial loam deposited from repeated overflowings of the Thames, which are now prevented by banks or dykes. But an increased demand for vegetables has caused much inferior soils to be cultivated as gardens, and increased labour and manure have supplied the deficiency in natural fertility. The gardeners' year properly begins in autumn, when the land is dug, or rather trenched, and well manured. Various vegetables, which will be required in winter, are now sown, and especially those which are to produce plants to be set out in spring; spinach, onions, radishes, and winter salads are sown, and when the weather is severe, are protected by a slight covering of straw or mats. In February, the cauliflowers which have been raised in frames or under hand-glasses are planted out. The cabbage plants are pricked out. The radishes, onions, and salads go to market as soon as they are of sufficient size, and sugar-loaf cabbages succeed them. As the cauliflowers are taken off, they are succeeded by endive and celery, and the same is the case with the cabbages. Thus there is a constant succession of vegetables, without one moment's respite to the ground, which, in consequence of continual stirring and manuring maintains its productive power. Deep trenching in some degree prevents that peculiar deterioration of the soil which would be the consequence of the frequent repetition of similar plants. This effect is most perceptible when the plants perfect their seed, which is seldom or never allowed to take place in market gardens; but great attention is paid to the species of plants which succeed each other on the same spot. The principle which experience and theory unite in establishing, is that of avoiding the too frequent recurrence of plants which belong to the same natural families. The great variety cultivated in gardens, in comparison with the common produce on a farm, enables this principle to be fully acted upon. Those gardeners who overlook this, and repeatedly sow or plant the same kind of vegetables in the same spots, are soon aware of their error by the diminution of the produce, both in quantity and quality, and by various diseases which attack the plants, however abundant may be the food supplied to them, or careful the tillage.

The principle on which the gardens are cultivated, is that of forcing vegetation by means of an abundant supply of dung, constant tillage, and occasional watering. The whole surface is converted into a species of hotbed; and crop succeeds crop with a rapidity which is truly astonishing. Those vegetables which arrive at a marketable state in the least time are always the most profitable, and those also for which there is a constant demand at all times of the year. With an abundant supply of manure, the market gardeners have no fear of exhausting the soil; and dissimilar vegetables may grow together on the same ground. Trees bearing fruit may be planted in rows, especially those of the dwarf kind; and under them those vegetables which do not require much sun may be raised to advantage. This is a very common arrangement in the market gardens near London. Raspberries, gooseberries, and currants, are planted in the rows between the trees. These rows being thirty or forty feet apart, leave ample room for vegetables. But in those gardens where the finest vegetables are raised, and particularly in those which are appropriated to the growth of seeds, no trees are permitted to shade the ground: even the hedges, if there are any, are kept low and clipped, that they may not give any shade, or harbour small birds. The market gardeners near London do not raise many peas or beans, except such as are forced and require glass frames to protect them. The chief supply of peas in the season comes from a greater distance, and is the produce of whole fields sown for that purpose by the farmers within a moderate distance of London. This crop would not be so profitable in a confined garden cultivated at a great expense.

The value of the produce in one year, from an acre of garden-ground in the most favourable situation, is almost incredible. The expenses of cultivation are very great. In inferior situations, where the produce is less, the expenses are also somewhat less.

A garden should always be laid out in a regular form, with narrow parallel beds, and paths between them. One or more roads, of sufficient width to allow a cart to pass, should intersect these beds at right angles, for the convenience of bringing manure and taking off the produce. The beds should not be above six feet wide; so that a person may easily pull up weeds, or gather the vegetables without treading upon the beds. The surface-soil taken from the paths serves to raise the beds, and in retentive soils may carry off the superfluous water after sudden and violent rains. The whole grounds should have been trenched two spits deep or more; and this trenching should be frequently repeated, to mix the upper with the under part of the soil, and distribute the decomposed dung throughout the whole depth. Thus in time a rich black mould will be produced, in which every kind of vegetable will grow most rapidly. For early plants, and those which are used in winter, and require to be protected from frost, narrow beds are made lying in a direction east and west, and sloping towards the south, with the north side raised high, so that their surface forms an angle of twenty or thirty degrees with the horizon. This gives the plants a protection from the north winds, and exposes them more to the influence of the sun. In very frosty weather, these beds are covered with mats or loose straw. We do not mention frames covered with glass, as they belong to a higher kind of horticulture: but a moderate hotbed made with fresh dung, and covered with mats laid over hoops, is indispensable for the raising of early vegetables. By these means radishes and various salads may be raised very early in the spring, and sometimes, in mild winters, without any interruption during the whole year.

An abundant supply of manure is indispensable in a market-garden, and this can generally be obtained in large towns at a trifling expense. The neighbourhood of a town is therefore a necessary circumstance towards the production of the crop, as well as its sale. It would be impossible to make a sufficient quantity of manure by means of the horses which are employed to carry the produce to market; and the extent of land usually laid out in garden-ground could not raise sufficient food for cattle, without taking up a space which may be more profitably employed. The only animal which can be kept to advantage by a gardener is a pig. This animal will live well on the offal of vegetables; and the gardens of cottagers could not well be kept in a fertile state if it were not for the manure made by the pigs.

The market-gardeners about Amsterdam are mostly Jews, and the vegetables which they bring to market are similar to those of the London or Paris gardeners; but they excel particularly in raising cauliflowers, large white cabbages for making *saur-kraut*, a dish much relished in the winter by the Dutch and Germans, [CABBAGE,] French beans, cucumbers and melons. They raise these last in such abundance, that heaps of them are sold in the markets at a very low rate. They also excel in the forcing of early peas and beans, and in the general management of hot beds.

The profits of a garden near London, of the extent of ten or twelve acres, are as great as that of a farm of ten times the extent cultivated in the best manner, without the help of purchased manure. But if manure can be obtained at a reasonable rate, as is often the case in great thoroughfares, where many horses are kept for public conveyances, although there be no immediate demand for vegetables, a garden may be very profitably cultivated, entirely for the purpose of raising seeds. This branch of industry is the more worthy of notice, as it may enable a cottager to improve his situation greatly by the produce of a small garden or allotment of land. The demand for seeds of all the most common productions of a garden, and especially of flowers, is great beyond belief, and the profit of those who retail them in small quantities is so great that they can afford a liberal price to those who raise them with proper care so as to keep the varieties distinct.

In some agricultural districts it is the custom for the labourers to plant turnips in their gardens in November, in order to obtain the seed in time for sowing in the next year. They choose the soundest and best shaped, and by attention in keeping the ground clean, and allowing only one sort to go to seed within a certain distance, they produce a better seed than the farmer could; because the labourer and his family having their garden constantly in view, can more easily keep off birds and watch the ripening of the seed, so as to allow it to come to perfect maturity, without danger of the pods bursting, and shedding the seed from being left too long. Thus they can collect a bushel or two of excellent seed from a small portion of land; and this, at the price of a guinea a bushel, which is cheaper to the farmer than if he raised it himself, or purchased it of the seedsman, is a very profitable crop to the labourer. An industrious cottager, without losing any time, with the help of his wife and children, may much increase his comforts in this manner, while at the same time he trains his children in habits of industry. To no class of men would a knowledge of garden husbandry be more useful. The improvement which may be made in the condition and character of the poor, by combining in their education a knowledge of the most common arts of life with that of letters, which is often the only thing taught in schools, must be evident to every man who has reflected on the subject; and of all these arts the most generally useful amongst an agricultural population is the art of horticulture. The cottager who is acquainted with the means of raising early garden produce, who can graft young trees, who knows what plants may be propagated with a little care, and be readily sold when in perfection, cam employ his labour with a double advantage. And many a man, from a very small beginning, has, with a moderate share of judgment and prudence raised himself to independence, if not to affluence; while he that plods on in the beaten track like a horse in a mill ends his days in ignorance and poverty.

The great superiority of those schools which have been established to teach the children of the poor to work as well as to read, over those which teach book knowledge only, is indisputable. A boy who can manage a little garden, who takes a pleasure in watching the seed he has sown, who plucks out every weed as soon as it appears, and who prides himself on the fruit and vegetables which he can place on his father's table, is more advanced in his education than he who can only read and write, however well he may do both.

Many plans have been proposed for the distribution of the crops in a cottage garden; but none of them are suited to every situation. Much depends on the nature of the soil, which may be better suited to one kind of produce than another; and also to the demand for any peculiar class of vegetables. New sorts may often be introduced with advantage. The raising of any useful plant with great care will often give a man a reputation, which makes it advantageous to him to confine himself to these principally, and raise them in the greatest perfection. An ingenious man will find out what is most for his own advantage; and from the list of plants which may be cultivated for ornament, or for use, a selection may be made which may be well suited to the situation of the ground and the circumstances of the grower. The practice of the market-gardeners may be examined with advantage; and long experience, with the test of profit, will lay down better practical rules than the most plausible theories.

An allotment of land, such as is now very frequently given to agricultural labourers, may be cultivated to great advantage by applying judiciously the general principles of garden husbandry. There are few cottages which have not already attached to them a small garden of a few perches, in which common vegetables, such as cabbages, onions, and early potatoes, are raised. The same vegetables may continue to be cultivated there, provided the situation is more convenient from its proximity to the cottage, or a small part of the allotment may be set apart every year for this purpose, so as to change the crops, which is always an advantage. But the remainder of the allotment should be cultivated on a regular plan, as a farm in miniature, with this difference, that all the operations should be performed with the minute attention of a gardener. Potatoes and wheat, if the soil is not too light for the latter, or rye, in very sandy soils, will be the principal crops, being immediately necessary to the support of the family. These crops have sometimes been recommended to be raised in every alternate year; but whatever be the tillage or manuring, there are few soils which will not soon be reduced in fertility by this constant succession. One-fourth of the land in wheat, and one-fourth in potatoes, is the utmost which can be profitably cultivated in one year. The remaining half of the allotment must produce pulse, roots, and green crops, by which animals may be fed and manure collected. An allotment of three acres will enable a cottager to keep a cow, by having a portion of it in clover or other artificial grass. In the 'Farmer's Magazine,' for February, 1802 (p. 38), there is an article drawn up by Mr. John Sinclair, in which it is shown how this may be effected without difficulty. But as the allotments usually given to labourers seldom exceed half an acre, or at the most an acre, the keeping of a cow is out of the question; and the only animal which can be profitably reared and fatted is the pig, to which we shall therefore confine our observations. By means of pigs, the cottager may greatly increase the profit which can be made from his allotment of land, keeping up at the same time a proper degree of fertility. One-half of his land must be cultivated to feed his pigs; besides the smaller potatoes which remain when the finest and best are taken out for the use of the family, he may give them beans, barley, carrots, parsnips, and turnips, especially the Roota Baga, or Swedish turnip; and all the straw must be used for litter. If this be strictly attended to, the greatest possible profit will be made from the land, without any danger of its being exhausted and losing its fertility. The rotations will therefore be—potatoes, with a great quantity of manure; then barley, then peas, beans, carrots, parsnips, and Swedish turnips, manured; and after these wheat. The application of the garden husbandry must be in the preparation of the soil by deep trenching and digging, carefully drilling or dibbling all the seeds in rows, stirring the soil between the growing plants, and keeping the ground clear of weeds by the hand and the hoe. These last are the most essential part of the cultivation, and are to be performed by the wife and children. By daily attention to the progress of the plants, and continual assistance at critical periods, sometimes thinning out, and at other times transplanting to produce an equal crop, and treating every plant as if it were a rare plant in a garden, the ground may be made to produce more than double what the most attentive farmer could expect on a larger scale. The additional labour, which is all light, costs the cottager nothing; but the farmer could not afford to pay for it at the usual rate of wages. If he could find hands to do it, he could not insure the minute attention which is naturally applied when the labourer is to receive all the advantage himself. The comfort which a well-managed allotment gives to a labourer with a numerous family is hardly credible by those who have not witnessed it; and if there were less profit, it would still be highly beneficial, in a moral and political point of view, that early habits of industry should be encouraged, and that the temptations which arise from want of employment should be taken away from the young by the useful and healthy occupations of the garden.

Let us add that on the garden culture of London neighbourhood, by which vegetables are raised for the metropolitan markets, the reader should consult Mr. Cuthill's paper on market-gardening in Morton's 'Cyclopædia of Agriculture.' And as to allotment culture; while anything which shall distract the cottager from his hired labour as the main source of his maintenance is bad, and while therefore large allotments of one acre or more are generally mischievous in their influence, there cannot be a doubt that, on a smaller scale, as Mr. Morton states in the 'Journal of the Royal Agricultural Society of England' the so-called allotment system is beneficial both to the labourer and his employer. If the possession of a store of field and garden produce be, as is alleged, a temptation to dishonesty, by the facilities which it affords for secreting the property of an employer, it is even more powerfully and in a variety of ways a security for good behaviour. The allotment of land which provides this store attaches a man to the locality in which he lives—it provides employment for those hours both of his children and himself which would otherwise be wasted—it adds to the comforts of his home—and it is generally a subject of common interest to himself, his neighbour, and his superiors. All these things tend to make him both contented and respectable. And if, as has been also said, the cultivation of an allotment does prove a tax upon the powers of the labouring man, incapacitating him in some degree by its need of extra work for those ten hours' labour which are due to his employer, it must be remembered, on the other hand, that, by every addition to the comforts and the means of home which it confers, his strength for those ten hours' labour is increased.

The following account of the way in which the allotment system was established at Whitfield, in Gloucestershire, and of its influence there, and the character of the population, is taken from Mr. Morton's paper already alluded to. The system there was not necessarily called for by excessive population; there was no special difficulty felt either by employers in providing labour, or by workmen in obtaining a livelihood; it was carried into operation as an addition to the comforts of an already tolerably satisfactory condition of the agricultural labourer.

The Whitfield allotments were first let many years ago, and, after twelve or fourteen years' cultivation, they are as fertile and productive as ever. Lying near the hamlet where most of the tenants live, the land is cultivated by them with the least possible waste of labour in passing to and fro, and with the greatest facilities both for the conveyance of manure to the land and the removal of produce from it. Most of the plots are 60 or 70 perches in extent, varying, however, from less than a quarter of an acre to rather more than half an acre. The way in which the land was let, and the whole scheme organised, may be very shortly described. On application to the late Earl of Ducie, an old pasture close to the village, about 11 acres in extent, was set apart for the purpose. Twenty or thirty cottages stand around or near the field, and to each a plot of ground was allotted. The field was, in the first place, divided into pieces varying in size between the extremes already named, according to the number of the cottagers and their ability to manage it. Paths were made between certain clusters of these plots, and a cart-way was left at either end of the land, for the removal of the produce. Such portions of the field as needed it were effectually under-drained. One-half of each plot was then dug up a good spit deep with the grafting-tool. All this was done during the winter. Sheep were turned in during the following summer. The grass of the halves left undug was thus eaten bare, and the halves of the several plots that had been dug were thus well trodden down. The allotments were apportioned at Michaelmas by lot, each cottager being told in what class, as to size, he was permitted to draw. To those of less ability than the others, whether owing to greater distance from the field, to having fewer children able to assist, or to want of strength or skill, the smaller plots were offered. To those of greater ability, whether of greater need or not, the larger plots were offered. It was urged that to allow these plots as a mere makeshift in aid of the necessitous, would have a pauperising tendency. It was an opportunity to them, offered according to their ability, not according to their need; and it thus acted as a premium upon every good quality they possessed or could acquire.

The previous management of the land placed it in the hands of these allotment tenants in first-rate order: the half which had been dug six months or more before, and trodden down all the summer by the sheep, was in the best possible condition for receiving wheat; and the other half in grass was ready to be at once dug up for potatoes, beans, or other vegetables, during the ensuing spring. The new rent demanded was determined by charging, in addition to the former agricultural rent, 5 per cent. upon all that had been expended by the landlord in carrying out the scheme. The drainage of the land, the plotting and digging it, the loss of rent of the land half dug,—all these added together, constituted a principal sum, on which 5 per cent. was charged in addition to the former rent. To this was added the estimated rates and taxes, and the cost of keeping fences in repair, together with 1*s.* from each of the allotments (about 3*s.* an acre on an average); this last to constitute a prize fund in furtherance of good cultivation. The whole rent thus ascertained was allotted over the several plots in proportion to their size and the quality of the soil.

The only conditions imposed upon the tenant, beyond the regular payment of his half-yearly rent, were that he should cultivate the land by manual labour, that he should not crop more than half his land with wheat or potatoes, and should give up the whole at the end of a year if required to do so.

There can be no doubt that this eleven acre field has been a great addition to the comforts of the village of Whitfield; and any one who sees the whole village population, young and old, at work upon it during those evening and even moonlit hours of spring and autumn, which would otherwise by many of them have been worse than wasted in the beer-house, must feel that the good influence of these field-gardens extends, beyond the mere material condition, to the character as well. The latter consideration is less capable of definite estimate or proof—it is incapable of reference with certainty to its causes; but in valuation of the former, there is no doubt that many a half-acre in the Whitfield allotment-field, which formerly contributed perhaps one-sixth to the annual keep of a cow, now provides one-fourth the bread-corn needed by a family, with more than that proportion of the potatoes they consume. Thirteen or fourteen bushels of wheat, and more than two tons of potatoes, are thus obtained from many a half-acre of land. "I would rather have my plot and pay a heavy rent for it, than have a *5l.*-note for nothing once a year," is the common testimony. The rent does not exceed *8l.* an acre, and the land was probably worth *50s.* as a pasture-field. It is punctually paid.

The Michaelmas rent-day was signalised by the award of prizes, namely, 1*l.* to the best cultivated allotment, and a return of the half-year's rent to the second best; and for this funds, as has been said, were provided by the allottees themselves, in the additional rent taken from them for this purpose.

The influence of the allotment system has perhaps been better shown at Silsoe (Bedfordshire) than in any other place. Mr. Trethewy, of that place, read a paper on it at a recent meeting of the London Farmers' Club, and he declared it as his opinion, the result of a large experience, that the subject involved the comfort and prosperity of the occupier quite as much as of the owner of the land or of the labourer. "Any system having a tendency to elevate the moral character of the labourer and improve his condition must be worthy of encouragement by the farmer." Mr. Trethewy alluded to the special fitness of this system where labourers live in villages, and where sufficient garden-ground cannot be obtained adjoining to the cottages. In choosing a field near the village, for the purpose of allotments, he says:—"The *nature* more than the *quality* of the soil should be considered, for it is astonishing how much poor thin land is improvable by spade husbandry, while strong and heavy clays are wholly unfit for the purpose of allotments, no matter how well they may be drained."

The following are his very sensible remarks on the importance of confining the allotments to a manageable extent of mere garden ground:—

"My experience convinces me that a rood is sufficient under almost any circumstances; and the greatest error that has been committed has been the allotting of too much land to one individual. To dwell upon the evils arising from such a proceeding is scarcely necessary, as it must be obvious that without sufficient capital the occupation of land cannot be attended with profitable results. Some instances in confirmation of this view have come under my own observation, and I can confidently assert that, instead of the position of such men having improved, it has retrograded. Occupied nearly the whole of their time upon their own land, they can no longer be classed under the head of labourers, and they actually injure regular workmen by throwing their labour into the market at seasons of the year when the demand for it is unusually depressed. If it be argued that the restriction of the system would have the effect of preventing a labourer from improving his condition, and effectually debar him from rising in the world by his own industry, I would answer that I am not now discussing the relative advantages of large and small farms, but am confining myself to the agricultural labourer in the broad acceptation of the term. Every employer knows, and every man of common sense must feel, that it is as important to the farmer to have his regular men at work at all times, as it is to the manufacturer or tradesman, and that the business of the farm could not be carried on without such regularity. I regard it, then, as a fatal error for the labourer to follow any pursuit that would at all interfere with the claim of his employer upon him; for, be it remembered, that it is upon *hired* labour that the working man must chiefly depend for his subsistence; and any scheme that has a tendency to interfere with this his chief capital, must very shortly end in disappointment and distress."

The following account of the Silsoe allotments is taken from Mr. Morton's paper in the 'Journal of the Royal Agricultural Society:' They date from the enactment of the new Poor Law, and the early promoters of the scheme were driven to it by the pressure of the poor's rates. The improvement in the condition of the labourer there and elsewhere is, no doubt, partly the effect of the new Poor Law, which has taught him that his first dependence must be on his own exertions; but a share in that improvement around Silsoe must certainly be allowed to the allotment system as there established. At first the allotment tenantry were allowed a considerable extent of land apiece—two acres or more. As much, indeed, as they declared their ability to manage was allotted to each applicant. But as these have gradually fallen in or failed, they have been subdivided; and from a rood to half an acre is now the ordinary extent allowed. There have been no restrictions placed upon the cultivators of these plots, but such as are also laid upon the farmers of the district. There is no formal provision against Sunday labour or against immorality, nor are there any special legal securities taken for the relapse of the land to the owner in case he should require it. Every security, nevertheless, exists as to all these particulars in the general sense of propriety which prevails, as well as in the knowledge that sufficient power exists in the management to enforce it. On riding round these allotments late in May, 1859, we saw poppies, turnip-seed, onions, peas, and cabbages, in some cases grown to a large extent; but the ordinary crops were wheat and potatoes for home consumption. In a few instances the land is in the hands of market-gardeners; but, as a general rule, the allotments are occupied by agricultural and other labourers; and the following table, extracted from Mr. Trethewy's paper, gives their extent and their number in the several parishes, together with interesting details regarding parochial rates since the period of their establishment:—

Parish.	Population per census of 1851.	Area of Parishes.	Number of Allotments.	Acreage of Allotment Land.	Annual Average of Five Years' Parochial Rates to Lady-day.					Parochial Rates for the Years							
					1858.			1848.		1828.		1833.		1835.		1838.	
		Acres.		Acres.	s.	d.		s.	d.	s.	d.	s.	d.	s.	d.	s.	d.
Silsoe	755	2067	78	24	2	10	in the £ upon rateable value.	2	3	7	5	5	6	3	3	2	6
Clophill	1186	2317	180	55	4	4		4	0	7	4	6	9	3	4	4	9
Flitton	656	1020	163	140	5	2		4	10	13	0	9	0	6	0	4	0
Pulloxhill	688	1584	131	51	3	2		3	6	11	0	12	0	6	0	3	8
Upper Gravenhurst	357	895	66	24	4	4		4	3	7	9	5	6	3	2	4	10
Lower Gravenhurst	58	757			2	0		2	1	2	0	2	0	1	0	2	10
			618	294													

We conclude with Mr. Trethewy's statement of the superiority of these clustered field-gardens over detached cottage-gardens, and of the advantages of encouraging rivalry by an annual judgment of cultivation and exhibition of produce:—

"(1) Every man has the advantage of the experience of the whole field, and generally benefits by it; whereas in a garden there are not those opportunities. (2) How frequently does one see a garden overrun with weeds, overgrown with trees, bushes, and fences, absolutely excluding sun and air, and producing next to nothing to the cultivator! In an open field-allotment the sun and air are freely admitted; the land is more easily kept clean, and the state of cultivation patent to all the neighbourhood. (3) I believe example has a strong influence in promoting good and clean cultivation among all classes of occupiers. With a view to encourage it amongst the allotment tenants of the district, a society, called the "Silsoe and Ampthill Labourers' Friend Society," was established about seventeen years ago. It offers several prizes annually for competition, and great interest is excited among the exhibitors. This society is under the patronage of Earl de Grey, and has Lord Wensleydale as president; while the stewards consist entirely of tenant-farmers, who thus evince their sense of its usefulness. The subscribers comprise the clergy and gentry of the neighbourhood, and the exhibition is invariably fully attended. In fact, all classes unite to promote the object it has in view; and the result is, an exhibition of fruits, vegetables, &c., that would surprise any one who had never before witnessed it. I believe this to be a most useful institution; and, where allotments prevail to any extent, I would strongly recommend the establishment of similar associations."

The almost universal testimony of experience on this subject confirms the conclusion to which, after Mr. Trethewy's paper, the discussion before the Central Farmers' Club led—that the system may always be expected to benefit both labourers and their employers, excepting under extravagant misguidance or neglect; that is, excepting (1) where the land set apart for the purpose is altogether unsuitable in character, or (2) too distant from the cottages of the allottees, or (3) where an excessive extent is permitted to the tenantry, or (4) an excessive rent demanded from them, or, lastly (5), where the tenantry are left entirely to themselves, and no effort made to excite their rivalry or pride in good cultivation.

GARGOYLE, GORGOL, or GURGOYLE, in Gothic architecture, a spout which is carried out from parapets in order to discharge the water from roofs clear of the wall. Mediæval architects, who almost invariably made the subsidiary features of their buildings of an ornamental character, so as to conduce to the general effect, saw at an early period the service which these humble objects might be made to render. Instead of having merely plain projecting pipes for their spouts, they covered the pipe with a block of stone, which they carved in general accordance with the rest of the sculpture; but, regardful of the ignoble purpose to which it was applied, gave it a decidedly grotesque character. Sometimes it is a human figure in a constrained attitude and with a distorted countenance; sometimes an animal or a monster. Usually the water is made to pass through the open mouth, but sometimes it passes from a pipe concealed below. Occasionally the figures appear to be caricatures of particular persons or bodies of men; occasionally they are gross; but almost always, as we have said, they are grotesque. They appear to have been first used in the Early English style; and they were most prominent in that and the Decorated.

GARLIC, a hardy perennial plant with bulbous roots, found growing wild in the island of Sicily, and in several other parts of the south of Europe. In gardens it is cultivated chiefly on account of its bulbs, which are much used in cookery, and occasionally in medicine.

It is the *Allium sativum* of botanists, and is regularly grown for the market. For this purpose, a light tolerably rich soil is selected in a dry warm situation. The ground should be well dunged for the crop which precedes garlic, and not when the garlic is planted; because, when this is done, the bulbs are very apt to canker, and to be infested with maggots.

It may either be planted in beds or in rows; if in beds, the distance between the plants may be seven or eight inches; if in rows (which is most recommended), they may be one foot apart, and six inches between the plants in the row. In gardens where the soil is light and dry, the best season for planting is late in autumn; but where the soil is wet, the operation should be deferred until spring, that is, to any time in February or March.

The plant is propagated by offsets, which it produces annually in considerable numbers, and which are commonly called cloves. The season of ripeness, which is generally in the end of July or August, is easily known by the leaves changing from green to yellow. At this period the bulbs should be taken up and spread out in the sun to dry, after which they may be tied in bunches and kept in a dry house for winter use, in the same way as onions.

GARLIC, OIL OF. When cloves of garlic [ALLIUM SATIVUM, in NAT. HIST. DIV.] are distilled with water in the manner described under ESSENTIAL OILS, 0·2 per cent of an oil is obtained of yellow colour, acrid taste, and strong disagreeable smell. After drying with chloride of calcium, and rectifying over potassium, it is obtained pure and colourless. It then constitutes the *sulphide of* the radical *allyl* (C_6H_5) [ORGANIC RADICALS] and has the formula (C_6H_5,S). The oxide of allyl, and a compound of allyl still richer in sulphur than the sulphide, appear also to be contained in the crude oil of garlic.

Sulphide of allyl is lighter than water, refracts light strongly, may be distilled without undergoing decomposition, is but slightly soluble in water, but very soluble in alcohol or ether. Sulphuric acid dissolves it without alteration, nitric acid converts it into oxalic and formic acids. On the addition of nitrate of silver to it, sulphide of silver is precipitated, and after a time crystals of double nitrate of silver and allyl are deposited. Sulphide of allyl also precipitates and forms double salts with the salts of gold, mercury, platinum, and palladium.

The mercury compound ($C_6H_5S,2HgS + C_6H_5Cl,2HgCl$) is decomposed on being distilled with sulphocyanide of potassium, sulphide of allyl being reproduced together with sulphocyanide of allyl (oil of mustard).

Other plants besides garlic contain sulphide of allyl; see ESSENTIAL OILS, *alliaria*, *cress*, *onion*, *radish*, &c.

GARNISHEE. [ATTACHMENT.]

GARTER, ORDER OF THE, one of the most ancient and illustrious of the military orders of knighthood in Europe, was founded by King Edward III. The precise year of its institution has been disputed, though all authorities agree that it was established at Windsor after the celebration of a tournament. Froissart says, Edward established the order on resolving to rebuild Windsor Castle, "which King Arthur had founded in time past," and fixed the first celebration of the order on "St. George's day next ensuing," that is April 23. 1344. Walsingham and Fabyan agree with this as the date of its foundation. Stow, who, according to Ashmole, is corroborated by the statutes of the Order, says 1350. Camden says it was founded after the battle of Crecy, at which Edward displayed his garter as a signal for the attack. The precise cause of the origin or formation of the Order is likewise not distinctly known. The common story respecting the fall of the Countess of Salisbury's garter at a ball, which was picked up by the king, and his retort to those who smiled at the action, *Honi soit qui mal y pense*, which afterwards became the motto of the order, is not entirely given up as fable. A tradition certainly obtained as far back as the time of Henry VI. that this Order received its origin from the fair sex. Ashmole's opinion was, that the Garter was selected at once as a symbol of union and a compliment to the ladies.

This Order was founded in honour of the Holy Trinity, the Virgin Mary, St. George, and St. Edward the Confessor. St. George, who had become the tutelary saint of England, was considered as its especial patron and protector. It was originally composed of twenty-five knights, and the sovereign (who nominates the other knights), twenty-six in all. This number received no alteration till the reign of George III., when it was directed that princes of the royal family and illustrious foreigners on whom the honour might be conferred should not be included. The number of these extra-knights was fifteen in 1860. The military knights of Windsor are also considered as an adjunct of the Order of the Garter.

The officers of the Order are a prelate, who is always the Bishop of Winchester; a chancellor, who till 1837 was the Bishop of Salisbury, but is now the Bishop of Oxford, in consequence of Berkshire, and of course Windsor, being transferred to that diocese; a registrar, who is the Dean of Windsor; garter principal king-at-arms of the Order; and a gentleman usher of the black rod. The chapter ought to meet every year on St. George's day, in St. George's chapel, Windsor, where the installations of the Order are held, and in which the banners of the several knights are suspended.

The original dress of the Knights of the Garter was a mantle, tunic, and capuchin or hood, of the fashion of the time, all of blue cloth; those of the knights companions differing only from the sovereign's by the tunic being lined with miniver instead of ermine. All the three garments were embroidered with garters of blue and gold, the mantle having one larger than all the rest on the left shoulder. The dress underwent various changes. Henry VIII. remodelled both it and the statutes of the Order, and gave the knights the collar, and the greater and lesser George, as at present worn. The last alteration in the dress took place in the reign of Charles II.: the principal parts of it consist of a mantle of dark blue velvet lined with white taffeta, and a surcoat of crimson velvet lined with white taffeta; a hood of crimson velvet; a cap or hat of black velvet lined with white taffeta, with an ostrich and heron plume; the stockings are of white silk, and the garter, which is of dark blue velvet, having the motto embroidered in gold letters, is worn under the left knee. The collar is of gold, of twenty-six pieces, each in the form of a garter, enamelled azure, appended to which is "the greater George," a figure of St. George encountering the dragon. The badge is a gold medallion representing St. George and the dragon, which is worn suspended over the left shoulder by a blue ribbon; hence it is a form of speech to say, when an individual has been appointed a knight of the garter, that he has received the blue ribbon. There is also a star of eight points argent, St. George's cross in the centre gules, encircled with the garter, worn on the left breast. The fashion of wearing the blue ribbon suspended from the left shoulder was adopted in the latter part of the reign of Charles II.

It is not generally known that, from the first institution of the Order of the Garter to at least as late as the reign of Edward IV., ladies were admitted to a participation in the honours of the fraternity. The queen, some of the knights-companions' wives, and other great ladies, had robes and hoods of the gift of the sovereign, the former garnished with little embroidered garters. The ensign of the garter was also delivered to them, and they were expressly termed *Dames de la fraternité de St. George*. The splendid appearance of Queen Philippa at the first grand feast of the Order is noticed by Froissart. Two monuments also are still existing which bear figures of ladies wearing the garter: the Duchess of Suffolk's, at Ewelme, in Oxfordshire, of the time of Henry VI., represents her wearing it on the wrist, in the manner of a bracelet; Lady Harcourt, at Stanton Harcourt, in Oxfordshire, of the time of Edward IV., wears the garter on her left arm above the elbow.

When Queen Anne attended the thanksgiving at St. Paul's in 1702, and again in 1704, she wore the garter set with diamonds, as sovereign of the Order, tied round her left arm.

GAS, a term originally employed by chemists as synonymous with air. It was first used in a very general sense by Van Helmont; but in consequence of the great number of permanently elastic fluids discovered by Priestley, so different in their properties from common air, and in order to avoid any confusion from the use of the same word to express both, Macquer employed the term gas, which has been universally adopted to distinguish from mere vapours all such elastic fluids as had not been rendered liquid or solid by reducing their temperature.

The experiments of Professor Faraday have however shown that elastic fluids which may be liquefied by reducing the temperature and increasing the pressure, are included in this definition. [GASES, LIQUEFACTION OF.] Still however there exists this difference between bodies in the elastic state:—vapours generated by the agency of artificial heat are reduced to solids or liquids when the heat is withdrawn; while gases preserve their aëriform state at common temperatures. It must however be admitted that the difference is one of degree only, and though not an essential one, it is usefully retained.

The number of gaseous bodies is great, and they possess in many respects such different properties, that it would be impossible to give a general description of them. The qualities therefore peculiar to each gas will be stated under its proper head; thus it will appear that some gases are elementary or simple in their nature, while by far the greater number are compound bodies; few of them exist in nature, but are mostly the products of chemical agency. Gases differ as to colour, odour, taste, specific gravity, and solubility in water; they vary also in their effects upon the animal economy, and in their relations to heat: most of them are either combustible or supporters of combustion, but one important gas at least belongs to neither class. Their powers of chemical combination are also extremely different; two gases only possess alkaline properties, whilst there are several gaseous acids.

One most important circumstance relative to gaseous bodies has been much discussed, and very opposite conclusions have been arrived at respecting it by philosophers of eminence; it is this, whether all gases, under the same volume and pressure, have the same specific heat. That this is the case, has been maintained by Haycraft, and Marcet and Delarive, and some others; while Dalton, Delaroche and Berard, Dulong and Dr. Apjohn, &c., are of opinion that equal volumes of different gases have not the same specific heat under similar circumstances.

It would be useless to detail the processes or to describe the apparatus by which chemists and physicists have arrived at such discordant results. The experiments of Delaroche and Berard, which are in general most relied upon, though complicated, were made with great care; they transmitted known quantities of gas, heated to 212° in a uniform current, through a calorimeter, the serpentine of which was surrounded with water, the temperature of which, as well as of the gas at its exit, being ascertained during the course of the process by very delicate thermometers. These chemists operated with a considerable quantity of gas, and used other precautions to avoid the errors into which other experimentalists had fallen.

The following is a statement of the results obtained by Delaroche and Berard, Dulong, and Apjohn, of the specific heats of equal volumes of the gases mentioned, under equal pressures:—

	Delaroche and Berard.	Dulong.	Apjohn.
Atmospheric air . . .	1·000	1·000	1·000
Nitrogen	1·000	1·000	1·048
Oxygen	·976	1·000	·808
Hydrogen	·903	1·300	1·459
Carbonic acid . . .	1·258	1.172	1·195
Carbonic oxide . . .	1·034	1·000	·996
Nitrous oxide . . .	1·350	1·159	1·193

Dr. Apjohn observes that the numbers which he has arrived at correspond tolerably well with those of Delaroche and Berard, except in the case of hydrogen; and he admits that he does not speak with much confidence of the numbers attached to nitrogen and oxygen.

There are some other properties which gases possess in common though they vary in degree. There is however one circumstance in which they all agree, whether they are elementary or compound, and whatever may be the difference of their specific gravity: they are subject to suffer the same increase of volume, when subjected to the same increase of temperature.

According to Dalton, when 100 volumes of air are heated from 32° to 212°, they become 132·5 volumes; by Gay-Lussac's experiments they increase to 137·5 volumes; by Crichton's to 137·48: the expansion therefore of each volume, according to Dalton is $\frac{1}{554}$, to Gay-Lussac $\frac{1}{480}$, and to Crichton $\frac{1}{480\cdot 25}$ for one degree of Fahrenheit's thermometer.

The discovery of this law has supplied chemists with a simple rule for determining what the known bulk of a gas at any temperature will be at any other temperature. Suppose, for example, it is desired to know what the bulk of 100 cubic inches of air at 32° will be at 60°;

subtract 32 from 480, the remainder is 448; to which add the degrees above zero indicating the temperature of the air, these are 32° and 60°, making 480 and 508. Then say 480 : 508 : : 100 : 105 · 832, the volume of the air at 60°.

It is well known that air suffers diminution of volume in proportion to the pressure to which it is subjected, and the same law holds good with all the more incondensible gases. In chemical analyses it is often requisite to make corrections for variations of barometric pressure, as well as of temperature in estimating the quantity of gaseous products. The following are the rules for this purpose, given by Professor Faraday in his work on chemical manipulation:—"A pressure of 30 inches of mercury, as observed by an accurate barometer, has been assumed as the *mean height* or *barometric pressure*, and volumes of gas observed at any other pressure frequently require to be corrected to what they would be at this point. For this purpose it is only necessary to compare the observed height with the mean height, or 30 inches, and increase or diminish the observed volume inversely in the same proportion. Thus, as the mean height of the barometer is to the observed height, so is the observed volume to the volume required. As an instance, suppose that 100 cubic inches of gas have been observed when the barometer stood at 30·7 inches: then, as 30 inches, or mean height, is to 30·7 inches, or observed height, so is 100, or the observed volume to a fourth proportional, obtained by multiplying the second and third terms, and dividing by the first: thus, $30{\cdot}7 \times 100 = 3070$, which divided by $30 = 102{\cdot}333$ cubic inches; this would be the volume of the gas at 30 inches of barometric pressure. Again, suppose a quantity of gas amounting to 20 cubic inches standing over mercury in a jar, the level of the metal within being 3 inches above that without, and the barometer at 29·4 inches. Then the column of 3 inches mercury within the jar, counterbalancing 3 inches of barometric pressure, instead of being 29·4, the latter is effectively only 26·4, and the correction will be, as 30 inches is to 26·4 inches, so is the 20 cubic inches observed to 17·6 cubic inches, the volume which the gas would really occupy if the mercury were level within and without the jar, and the barometer were 30 inches."

It is very commonly requisite to make corrections both for temperature and pressure in the same volume of gas, and it is of no consequence which is made first.

In chemical analyses various other considerations arise in ascertaining the quantities of gaseous products; as for example, the separation of or making the requisite allowances for the moisture which they contain: for these, as well as for the various modes of collecting, transferring, and preserving various gases, we must refer to the very excellent work just quoted.

The solubility of gases in water is extremely various. Dr. Henry thought that the volume of each gas absorbed by water is the same, whatever be the pressure to which the gas is previously subjected, but this has since been proved to be not strictly correct. If the weight of carbonic acid gas be doubled by subjecting it to the pressure of two atmospheres, water will still absorb its own volume of it. The following table exhibits the volumes of each gas absorbed by 100 volumes of water at 60° Fahr., and under a pressure of 30 inches of mercury:—

	Absorption in Volumes.	Authority.
Cyanogen	450	Gay-Lussac.
Sulphuretted hydrogen	366·6	Thomson.
Chlorine	200	Berthollet.
Carbonic acid	106	Cavendish.
Nitrous oxide	76	Saussure.
Olefiant gas	15·3	Saussure.
Phosphuretted hydrogen	5	Thomson.
Nitric oxide	3·7	Dalton.
Oxygen	3·7	Henry.
Carburetted hydrogen	3·7	Dalton.
Azote	2·5	Dalton.
Carbonic oxide	2·01	Henry.
Hydrogen	2	Dalton.

It may be observed, that in general the more easily a gas is condensable by cold and pressure, the more soluble it is in water: this will appear by comparing the above statements with that containing the pressure at which Faraday liquefied various gases. For more recent and accurate researches on the solubility of gases in water at different temperatures, see Bunsen's 'Gasometric Analysis,' translated by Dr. Roscoe.

A curious property of gases, and possessed by them in very different degrees, is that of their condensation by porous bodies, and especially by charcoal. [CARBON.]

A curious fact with respect to mixtures of gases was discovered by Dr. Priestley, which he thus states: "Different kinds of air that have no affinity do not, when mixed together, separate spontaneously, but continue diffused through each other." This he proved to be the case by several experiments; and more especially by one, in which he found that he was able to explode hydrogen and oxygen gases, which had long remained together, and which he justly argues must have been mixed, or he could not have fired them by an electric spark, in a vessel, the wires of which were at the top. He adduces this experiment to illustrate the fact that the gases which constitute the atmosphere do not separate according to their respective gravities, though they do not combine. (Priestley's 'Experiments, &c.,' vol. vi. p. 391.)

These experiments were repeated by Dr. Dalton, and he inferred from them that the particles of one gas, though repulsive to each other, do not repel those of a different kind; and that one gas acts as a vacuum with respect to another. If therefore a vessel full of carbonic acid be made to communicate with another of hydrogen, the particles of each gas insinuate themselves between the particles of each other till they are equally diffused through both vessels. This theory accounts not only for the mixture of gases, but for the equable diffusion of vapours through gases and through each other.

Another observation made by Dr. Priestley, and related with others of a similar kind ('American Phil. Trans.,' vol. v.), appears to have been entirely overlooked. He found that though a glass vessel was perfectly air-tight, yet if it had been broken, and the pieces joined with paint or cement, hydrogen gas contained in it would be changed for the external air. Döbereiner has since remarked the escape of hydrogen gas by a fissure or crack in glass receivers. Professor Graham, in an elaborate paper on this subject, has shown that gases diffuse into atmospheric air and into each other, with different degrees of ease and rapidity, the lighter ones escaping most readily, so much indeed, that hydrogen escapes five times more quickly than carbonic acid gas, which is about 22 times heavier. [DIFFUSION.]

To Dr. Priestley also we are indebted for the important discovery that gases can pass through membranes which are perfectly air-tight, and by this action he explained that of the atmosphere upon the blood in the lungs. In the memoir above alluded to he has also shown, that when a bladder containing hydrogen is put into a vessel of oxygen, or one with oxygen into a vessel of hydrogen, the bladder and the vessel of gas both contain both gases, owing to the passage of the gases from and into the bladder. It is also stated by Professor Graham, that if a bladder, half filled with air, with its mouth tied, be passed up into a large jar filled with carbonic acid gas, standing over water, the bladder, in the course of twenty-four hours, becomes greatly distended by the insinuation of the carbonic acid through its substance, and may even burst, while a very little air escapes outwards from the bladder. This however he does not consider as a case of simple diffusion; the result depends, first, upon carbonic acid being a gas easily liquefied by the water in the substance of the membrane, and therefore the carbonic acid penetrates the membrane as a liquid; secondly, this liquid is in the highest degree volatile, and therefore evaporates very readily from the inner surface of the bladder into the air confined in it. The air in the bladder comes to be expanded in the same manner as if ether or any other volatile fluid was admitted into it. Professor Graham further observes, that in the experiments of Dr. Mitchell and Faust and others, in which gases passed through a sheet of caoutchouc, it is to be supposed that the gases were always liquefied in that substance, and penetrates through it in a fluid form; and it is also to be noticed, that it is generally those gases which are more easily liquefied by cold or pressure that pass most readily through both caoutchouc and humid membranes.

Dr. Mitchell found that the time required for the passage of equal volumes of different gases through the same membrane was—

1	minute with	ammonia.
2½	minutes with	hydrosulphuric acid.
3½	,, ,,	cyanogen.
5½	,, ,,	carbonic acid.
6½	,, ,,	nitrous oxide.
27½	,, ,,	arseniuretted hydrogen.
28	,, ,,	olefiant gas.
37½	,, ,,	hydrogen.
113	,, ,,	oxygen.
160	,, ,,	carbonic oxide.
And a much longer time with		nitrogen.

In concluding we may observe that gaseous bodies are of the highest importance, as connected not merely with the well-being, but even with the existence of animals: two of them, oxygen and nitrogen, form our atmosphere; two of them, hydrogen and oxygen, constitute water; oxygen united with silicon and various metals forms the greater part of the crust of our globe; and chlorine is one of the elements of common salt.

GAS-LIGHTING, *Chemistry of.* The manufacture and consumption of gas for illuminating purposes is a process involving applications of chemistry at almost every step. There are, however, three distinct portions of the operation, the successful carrying out of which peculiarly require a knowledge of certain chemical principles: namely, 1st, the generation of gas: 2nd, its purification; and 3rd, its combustion for the production of light. We will, therefore, consider these points seriatim.

I. *Generation of Gas.*—The generation of nearly all kinds of gas for illuminating purposes is a process termed by chemists *destructive distillation*, and consists in placing coal, or other similar substance, in close vessels heated to a temperature varying from a red to a white heat. In practice, the vessels used are generally retorts, constructed either of cast iron or clay. The organic substances thus heated consist almost entirely of the elements carbon, hydrogen and oxygen, with small pro portions of nitrogen and sulphur. On exposure to the heat of the retorts, the hydrogen escapes partly in a free state and partly combined with the other elements, carbon, oxygen, nitrogen, and sulphur; the oxygen combines partly with hydrogen, forming aqueous vapour, and partly with carbon, producing carbonic oxide and carbonic acid gases; the nitrogen is evolved chiefly as ammonia, but partly also as cyanogen; the sulphur chiefly as sulphuretted hydrogen, but likewise as bisulphide of carbon; whilst a considerable proportion of the most fixed element, the carbon, remains in the retort as *coke*. Several of the gaseous or volatile compounds thus formed unite with each other to form secondary compounds. Thus, portions of the carbonic acid, sulphuretted hydrogen, and cyanogen, unite with ammonia to form respectively, carbonate of ammonia, sulphide of ammonium, and cyanide of ammonium. After leaving the retorts, these volatile and gaseous matters are cooled down nearly to atmospheric temperature, when nearly all the vaporous matters condense, forming a liquid consisting of two layers, a lower one called *tar* [COAL TAR], and an upper one containing chiefly the ammoniacal compounds above mentioned dissolved in water. [GAS LIQUOR.] The permanently gaseous product of the operation is called *crude* or *impure gas*, and generally contains the whole of the following ingredients:—

	Name.	Chemical Formula.
Illuminating constituents.	Olefiant gas	C_4H_4
	Other hydrocarbons	CnHn
	Benzole	$C_{12}H_6$
	Other hydrocarbons	CnH(n − 6)
Diluents	Light carburetted hydrogen	C_2H_4
	Hydrogen	H
	Carbonic oxide	CO
Impurities	Carbonic acid	CO_2
	Sulphuretted hydrogen	HS
	Aqueous vapour	HO
	Ammonia	NH_3
	Bisulphide of carbon	CS_2

The total quantity of these constituents, as well as the relative proportions in which several of them are generated, depends greatly upon the temperature at which the distillation is conducted. As a general rule, the lower the temperature the less gas is produced, but the greater is its illuminating effect when burnt. On the other hand, when a higher temperature is employed, a large volume of gas, but of inferior quality, is obtained.

Abstracting the impurities in the above list, it will be seen that gas contains two classes of constituents: namely—luminiferous constituents, or gases yielding light on combustion; and diluents, or non-luminiferous constituents, gases which practically yield no light on combustion. To the first class alone is the illuminating power of gas due; but one, at least, of the non-luminiferous gases is also necessary in order to enable the first class of constituents to burn without smoke and consequent loss of light. The members of the first class are all decomposed slowly at a red, and rapidly at a white, heat, depositing a large amount of carbon in the solid form, and being resolved into non-luminous gases. It is therefore obvious that, in the process of gas-making, more or less of these valuable constituents must be thus decomposed; the amount depending, on the one hand, upon the length of time during which they are exposed to a high temperature, and on the other, upon the number of the particles of such constituents which come into contact with the heated walls of the retort. Two methods for the prevention of this decomposition present themselves. The first consists in the rapid removal of the gases from the retort, and the second in the dilution of the luminiferous gases, whilst still in the retort, by the admixture or injection of non-luminous constituents. The first of these remedies has been extensively applied in the form of exhausters, which greatly facilitate the escape of the gases from the retorts, whilst both remedial measures have been secured in White's process of gas manufacture, in which a current of non-luminous gases is made to sweep through the retort, and thus rapidly remove the decomposable luminiferous constituents. This latter process, however, though undoubtedly based upon sound philosophical principles, has not come into extensive use, owing to certain mechanical difficulties in carrying it out.

The objects to be kept in view in the generation of gas for illuminating purposes are the following:—

1. The formation of a due proportion of illuminating and non-illuminating constituents; so that, on the one hand, the combustion of the gas shall be perfect, and without the production of smoke or unpleasant odour; and, on the other, the volume of gas required to produce a certain amount of light shall not be too great. For the production of an amount of light equal to that of twenty sperm candles of six to the pound, a consumption of gas greater than five cubic feet per hour ought not to be required.

2. The extraction of the largest possible amount of gaseous illuminating compounds from a given weight of materials.

3. The presence of the largest possible proportion of hydrogen amongst the non-illuminating constituents, to the exclusion of light carburetted hydrogen and carbonic oxide, so as to produce the least amount of heat and atmospheric deterioration in the apartments where the gas is consumed.

II. *Purification of Gas.*—A reference to the list of substances contained in crude or impure gas, given above, shows that there are five distinct compounds, all of which must be regarded as impurities. Of these, however, two—namely, bisulphide of carbon and aqueous vapour—may be left out of consideration, since the first, although highly objectionable in gas, as the cause of the sulphurous odour always perceived when gas is burnt in unventilated apartments, cannot be removed by any practicable process; whilst the second, which does little harm except diminish to some extent the illuminating power of the gas, cannot readily be abstracted, owing to the hydraulic nature of the apparatus used for the storage and measurement of gas. The processes used for the purification of gas are therefore restricted to the removal of sulphuretted hydrogen, carbonic acid, and ammonia. One hundred volumes of crude gas contain on an average the following quantities of these impurities:—

Carbonic acid	2·5
Sulphuretted hydrogen	·8
Ammonia	15

The two chie ingredients used for their removal, with more or less success, are hydrate of lime and hydrated peroxide of iron.

The first was formerly used suspended in water as milk of lime, through which the gas was made to bubble; but it is now almost universally employed in the solid pulverulent form. By direct chemical affinity, the hydrate of lime removes only sulphuretted hydrogen and carbonic acid from the impure gas; but the water which it contains enables it also to remove the greater part, at least, of the ammonia. The sulphuretted hydrogen forms, with hydrate of lime, water and a non-volatile sulphide of calcium, according to the following equation:—

$$\mathrm{CaOHO + HS = CaS + 2HO.}$$

Carbonic acid is rapidly absorbed by hydrate of lime, forming a basic carbonate, thus:—

$$\mathrm{2(CaO\ HO) + CO_2 = }\underbrace{\mathrm{CaO\ CO_2 + CaO\ HO}}_{\text{Basic carbonate of lime.}}\mathrm{ + HO.}$$

In both these reactions water is set at liberty, which assists in absorbing and retaining ammonia as mentioned above.

When hydrated peroxide of iron is used for the purification of gas, the carbonic acid is totally unacted upon, but the ammonia is perhaps more completely absorbed than by the lime process. The carbonic acid is either subsequently absorbed by slaked lime or, as is more frequently the case, it is suffered to remain in the gas, occasioning a considerable loss of light, but no additional nuisance to the consumer. The action of hydrate and peroxide of iron in removing sulphuretted hydrogen consists in the formation of sulphide of iron, water and free sulphur, thus:—

$$\mathrm{Fe_2O_3, 3HO + 3HS = 2FeS + S + 6HO.}$$

The cost of hydrated peroxide of iron would effectually prevent its use, if, like lime, it were only once available for the purpose; but the peculiarity and value of this oxide as a purifying agent consist in its capability of *revivification*;—that is, restoration to its original condition, or nearly so. This is effected by simple exposure to atmospheric air, the oxygen of which is so rapidly absorbed by the sulphide of iron as to occasion considerable risk of ignition unless the supply of air be moderate. Hydrated oxide of iron is regenerated, and the sulphur previously combined with the iron is set at liberty in the following manner:—

$$\mathrm{2FeS + 3O + 3HO = Fe_2O_3, 3HO + 2S.}$$

This alternate absorption of sulphuretted hydrogen and revivification might probably be carried on for an infinite number of times, were it not that the free sulphur ultimately accumulates to such an extent as to greatly reduce the efficiency of the mixture, and the sulphur therefore requires occasional removal either by distillation or roasting.

As it reaches the consumer, gas is very rarely contaminated with even a trace of sulphuretted hydrogen, but it frequently contains carbonic acid and invariably bisulphide of carbon, to which latter substance, giving as it does sulphurous acid on combustion, nearly all the annoyance experienced from the use of gas in dwelling-houses is due. In conclusion, sulphuretted hydrogen may be readily detected in gas by allowing a jet of the latter to blow upon a piece of white paper moistened with a solution of acetate of lead; the slightest discoloration of the paper shows the presence of sulphuretted hydrogen. Carbonic acid is best detected by allowing the gas to bubble through clear and transparent lime-water which will become turbid if the acid gas be present. Ammonia is recognised by allowing a jet of the gas to blow against paper tinted yellow with infusion of turmeric; ammonia changes the yellow of this paper to reddish brown. Bisulphide of carbon is detected by condensing the aqueous vapour formed by a gas flame: if the condensed product redden litmus paper this impurity is present.

III. *The combustion of gas.*—The production of artificial light depends upon the fact, that at certain high temperatures all matter becomes luminous. The higher the temperature the greater is the intensity of the light emitted. The heat required to render matter luminous in its three states of aggregation differs greatly. Thus, solids are sometimes luminous at comparatively low temperatures, as phosphorous and phosphoric acids. Usually, however, solids require a temperature of 600° or 700° Fahr., to render them luminous in the dark; and must be heated to 1000° Fahr. before their luminosity becomes visible in daylight. Liquids require about the same temperature. But to render gases luminous, they must be exposed to an immensely higher temperature; even the intense heat generated by the oxhydrogen blowpipe scarcely suffices to render the aqueous vapour produced visibly luminous, although solids, such as lime, emit light of the most dazzling splendour when they are heated in this flame. Hence, those gases and vapours only can illuminate, which produce or deposit solid or liquid matter during their combustion. This dependence of light upon the production of solid matter is strikingly seen in the case of phosphorus, which when burnt in chlorine produces a light scarcely visible; but, when consumed in the air or oxygen, emits light of intense brilliancy; in the former case, the *vapour* of chloride of phosphorus is produced, in the latter *solid* phosphoric acid.

Several gases and vapours possess this property of depositing solid matter during combustion, but a few of the combinations of carbon and hydrogen are the only ones capable of practical application: these latter compounds evolve during combustion, only the same products as those generated in the respiratory process of animals, namely, carbonic acid and water. The solid particles of carbon which they deposit in the interior of the flame, and which are the source of light, are entirely consumed on arriving at its outer boundary; their use as sources of *artificial light*, under proper regulations, is therefore quite compatible with the most stringent sanatory rules.

The light emitted during the combustion of coal gas is due entirely to the illuminating class of its constituents, which yield an amount of light proportional to the quantity of carbon contained in a given volume; thus, *propylene* and *butylene* yield respectively 50 and 100 per cent. more light than olefiant gas, because they contain respectively 50 and 100 per cent. more carbon in a given volume.

It would not be desirable to employ a gas containing only luminiferous ingredients, even if it were possible to manufacture such a gas, because it is exceedingly difficult to consume these constituents without the production of smoke attendant on imperfect combustion. An inflammable diluting material is therefore necessary to give the flame a sufficient volume, so as to separate the particles of carbon farther asunder, and thus diminish the risk of their imperfect combustion.

All the three diluents above mentioned perform this office equally well; but if we study their behaviour during combustion we shall find that in a sanatory point of view hydrogen is greatly to be preferred.

The two objections most frequently urged against the use of gas in apartments are, first, the heat which it communicates to the atmosphere; and, second, the deterioration of the air by the production of carbonic acid. Now, in their action upon the atmosphere in which they are consumed, the above three diluents present striking differences in these two respects.

One cubic foot of light carburetted hydrogen, at 60° Fahr., and 30 inches barometrical pressure, consumes two cubic feet of oxygen during its combustion, and generates one cubic foot of carbonic acid, yielding a quantity of heat capable of heating 5 lbs. 14 oz. of water from 32° to 212°; or causing a rise of temperature from 60° to 80·8° in a room containing 2500 cubic feet of air.

One cubic foot of carbonic oxide at the same temperature and pressure, consumes during combustion half a cubic foot of oxygen, generates one cubic foot of carbonic acid, and affords heat capable of raising the temperature of 1 lb. 14 oz. of water from 32° to 212°; or that of 2500 cubic feet of air from 60° to 66·6°.

One cubic foot of hydrogen at the same temperature and pressure, consumes half a cubic foot of oxygen, generates no carbonic acid, and yields heat capable of raising the temperature of 1 lb. 13 oz. of water from 32° to 212°; or that of 2500 cubic feet of air from 60° to 66·4°.

This comparison shows the great advantage which hydrogen possesses over the other diluents, especially over light carburetted hydrogen, which is evidently a very objectionable constituent, and shows that a normal gas for illuminating purposes should consist of illuminating hydrocarbons diluted with pure hydrogen.

As an illuminating agent gas is superior to all others in an economical point of view, as seen from the following table, showing the comparative cost of light from various sources equal to 20 sperm candles, each burning for 10 hours at the rate of 120 grains per hour:—

	s.	*d.*
Wax	7	2½
Spermaceti	6	8
Tallow	2	8
Sperm oil (Carcel's lamp)	1	10
London gas	0	4½
Manchester gas	0	3
Liverpool gas	0	2½

As regards the production of a minimum amount of carbonic acid and heat, gas is also greatly superior to other light-giving agents, as will be seen from the following comparison, showing the absolute amounts of carbonic acid and the relative quantities of heat generated per hour, by various sources of light each equal to 20 sperm candles burning at the rate of 120 grains per hour:—

	Carbonic Acid.	Heat.
Tallow	10·1 cubic feet.	100
Wax . . . . . Spermaceti . . .	8·3 ,,	82
Sperm oil (Carcel's lamp) . .	6·4 ,,	63
London gas	5·0 ,,	47
Manchester gas	4·0 ,,	32
Liverpool gas	3·0 ,,	22

Notwithstanding the great economy and convenience attending the use of gas, and in a sanatory point of view, the high position which, as an illuminating agent, coal gas of proper composition occupies, its use in dwelling-houses is still extensively objected to. The objections are partly well founded and partly groundless. As is evident from the foregoing table, even the worst London gases produce, for a given amount of light, less carbonic acid and heat than either lamps or candles; but then, where gas is used, the consumer is never satisfied with a light equal in brilliancy only to that of lamps or candles, and consequently, when three or four times the amount of light is produced from a gas of bad composition, the heat and atmospheric deterioration greatly exceed the corresponding effects produced by the other means of illumination: but by using a gas of high illuminating power, like those of Liverpool or Manchester, it is evident that two or three times the light may be employed with the production of no greater heat or atmospheric deterioration than that caused by wax candles, or the best constructed oil lamps.

But there is nevertheless a real objection to the employment of gas-light in apartments, founded upon the production of sulphurous acid during its combustion; this sulphurous acid is derived from bisulphide of carbon, which has already been referred to as incapable of removal from the gas by the present methods of purification.

This impurity, which is more or less encountered in all coal-gas now used, is the principal, if not the only, source of the unpleasant symptoms experienced by many sensitive persons in rooms lighted with gas. It is also owing to the sulphurous acid generated during the combustion of this impurity, that the use of gas is found to injure the binding of books, and impair or destroy the delicate colours of tapestry; therefore the production of gas free from this noxious sulphur compound is at the present moment a problem of the highest importance to the gas manufacturer, and one which demands his earnest attention.

As it is impossible for the consumer to procure gas free from this objectionable compound, the only method of obviating its unpleasant and noxious effects, is to remove entirely the products of combustion from the apartments in which the gas is consumed, and thus prevent them from mingling with the circumambient air. This suggestion was first made by Faraday, who accomplished this object by his very beautiful and effective ventilating burner. This apparatus, which is used at Buckingham Palace, Windsor Castle, the House of Peers, and in many public buildings, may be truly said to have brought gas illumination to perfection; for not only are all the products of combustion conveyed at once into the open air, but nearly the whole of the heat is in like manner prevented from communicating itself to the atmosphere of the room. The only obstacles to the universal adoption of this description of burner are its expense, and the difficulty of conveying the ventilating tube safely into the nearest flue without injuring the architectural appearance of the room. The public at large will therefore still await the removal of the objectionable compound in question, by the gas manufacturer, before they will universally adopt this otherwise delightful means of artificial illumination. For the method of analysing gas, and for the chemical mode of determining its illuminating power, see GASOMETRIC ANALYSIS, *Analysis of Coal Gas.*

GAS LIQUOR. In the manufacture of gas for illuminating purposes, by the destructive distillation of coal, certain liquid products are always obtained. Evolved from the heated coal in the state of vapour, they condense by the mere cooling of the gas, and then separate into two portions, the one having an oily character and constituting *coal-tar* [COAL-TAR]; the other being water containing some matters in solution, and known as *gas-liquor*, or the ammoniacal liquor of the gas-works.

The substances contained in this solution are ammoniacal gas, and the following compounds of ammonia with volatile acids:—

Carbonate of ammonia,
Sulphate of ammonia,
Sulphide of ammonium,
Chloride of ammonium,
Ferrocyanide of ammonium.

On account of the immense demand for ammoniacal salts by metallurgists, calico-printers, colour-makers, artificial manure manufacturers, and others, gas-liquor, although a secondary product in gas-manufacture, is of considerable commercial value. The various methods that a knowledge of chemistry would suggest for the extraction and working of the ammonia contained in gas-liquor have consequently formed the basis for much speculation, and many patents embodying those methods have been taken out. For some purposes it is sufficient to add hydrochloric or sulphuric acids to the crude gas-liquor, to well agitate the mixture, allow impurities to subside, concentrate to the crystallising point, and expose the crystals to a slightly elevated temperature. The resulting salt is still of course very impure, but serves for the preparation of carbonate of ammonia by sublimation with chalk; or certain portions of the impure chloride alone may be farther purified by sublimation. For purposes in which purer ammoniacal salts are desired, the ammonia is displaced from its combinations in gas-liquor by a stronger base, usually lime; it is separated from the resulting lime-salts and impurities by distillatory processes, and its vapour condensed in water containing the acids with which it is wished to unite it. From these solutions the salts are obtained by evaporation and crystallisation.

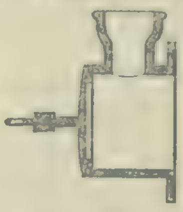
For a list of, and details concerning the various patented processes for "the manufacture of ammonia and ammoniacal salts from the ammoniacal waters of coal gas-works," see 'Pharmaceutical Journal,' vol. xiii., first series, pp. 63 and 113.

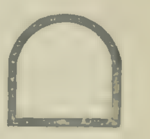
GAS, MANUFACTURE OF. There are few more remarkable illustrations of the occasional stagnation of human invention for long periods, and of its subsequent feverish activity, than may be discovered in the history of artificial lighting. It is true that from a passage in Ammianus Marcellinus, in which he speaks of the towns in the time of Constantius, A.D. 353, and says that it was easy for conspirators to carry on their treason in them, "ubi pernoctantium luminum claritudo dierum solet imitare fulgorem," it may be supposed that the ancients paid some attention to the lighting of their streets, but the most elaborate critical investigations, and the most careful observations upon the remains of antiquity, have failed to discover traces of any other system of lighting amongst the Greeks or Romans, than very rude oil lamps without chimnies, candles of very imperfect manufacture, torches, or open coal fires. The same methods of public and of private lighting were retained, without improvement, throughout the middle ages; nor was it indeed until about the end of the 17th century that anything like a regular system of public lighting was attempted in any of the capitals of Europe. The first decided steps towards the improvement of this important detail of domestic comfort and public security, seems to have been taken under the guidance of M. de Sartines; for under his protection Laugrin introduced the reflector lamps, which were subsequently improved by Quinquet; and finally Argand perfected the ordinary oil lamps, by the introduction of the cylindrical wick and chimney, with a double current of air. Letters patent for this invention were granted on 5th January, 1787, but they were abolished during the French revolution of 1793.

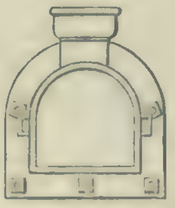
Whilst the methods of artificial lighting were thus slowly progressing in the beaten track, Mr. Murdoch was engaged in experiments on the combustion of coal gas; and in 1792 he lighted his house and offices at Redruth in Cornwall, by that means. In 1798, Murdoch also lighted the shops of Messrs. Bolton and Watt at Soho with "inflammable gas;" and in 1802 it appears that a M. Lebon proposed to light a portion of Paris in a similar manner. The Jesuits' College at Stonyhurst, was amongst the earliest public institutions to adopt the "new light;" and it was in the course of executing this work that Mr. Clegg introduced the method of purifying the gas by passing it through lime water; this took place about 1807. In the same year Mr. Winsor, who had taken a very conspicuous part in diffusing the knowledge of the new method of lighting, obtained permission to apply his apparatus to a few lamps in Pall Mall. The first act for the establishment of a gas company was passed in 1810, and under its powers the Chartered Gas Company commenced operations, in spite of the sneers of scientific men and the opposition of practical ones. It was not until the 31st of December, 1813, that gas lighting was employed on a large scale in streets, by the lighting of Westminster Bridge; and on April 1st, 1814, the parish of St. Margaret's Westminster substituted gas for oil throughout their district. About the beginning of the year 1820 Paris imitated the example thus set; and subsequently to that period almost every city of importance in England, and on the continent, has adopted the use of gas. The meter, for registering the consumption of gas, was invented in the year 1815 by Mr. Crosley, and since that period gas has been commonly applied in lighting private houses. It may convey some idea of the importance of the gas manufacture of London to state here that there are no less than nineteen companies established for this purpose, with a paid up capital of nearly six millions sterling.

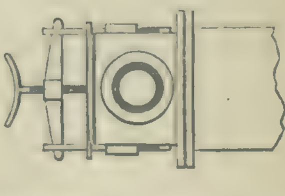
The manufacture of gas is conducted upon rather different principles in the large establishments of such a town as London, from those observed in the majority of small country works; and it will therefore be desirable to notice in detail the various processes of the manufacture, in order to explain some of the reasons for these particular variations. In so doing, the system to be observed is that of the ordinary course of manufacture; or to discuss, 1st, the carbonisation and distillation of the coal; 2nd, the condensation and purification; 3rd, the storage of the gas; 4th, the distribution, under the sub-divisions of the mains and of the fittings; and 5th, the accessory buildings, or processes employed. The conditions connected with the discharge of the public service by private companies, or by municipal bodies, will form the subject of a special article [PUBLIC LIGHTING], on account of the warm discussions which have lately taken place, and of the singular differences of system which prevail in the matter.

1. The distillation of the coal, or the process by means of which the illuminating gases are separated from the solid carbon of the coal, is effected in close vessels known by the name of *retorts*. These retorts are at the present day long, closed, horizontal vessels of cast iron, or of fire clay, or occasionally in large town-works they are built up with fire bricks; and, as might be expected, they are of every variety of form and cubical capacity. Generally speaking, however, retorts of cast iron are made of the shape of the letter D, and they are about 7 feet 6 inches long, by 20 inches wide, and 12 inches deep; their capacity being such as to allow them to carbonise 120 lbs of coal in each charge. The clay retorts are sometimes made of the same form and dimensions as the iron ones, but they are very frequently made perfectly cylindrical; or in large works they are made in lengths of about 16 inches, joined together with fire clay, so as, in fact, to form ovens about 7 feet long by 5 feet wide, and 18 inches high, as in some of Mr. Grafton's works; or, as in the case of the Phœnix Works, London, they are put together in three pieces, making retorts of 20 feet long, by 16 inches diameter. There are numerous descriptions of retort ovens formed of fire tiles and bricks now in use in the London gas factories, such as those for instance of the Westminster station of the Chartered Company, which are about 22 feet clear length, by about 20 inches wide, and 13 high, and are fed from both ends; or again in Paris, and at the London Gas Works, Vauxhall, a large oven is occasionally used, capable of carbonising as much as six tons of coals at a time, for the purpose of obtaining a description of coke adapted for foundry, or other analogous purposes, at the same time that the illuminating gases are secured.



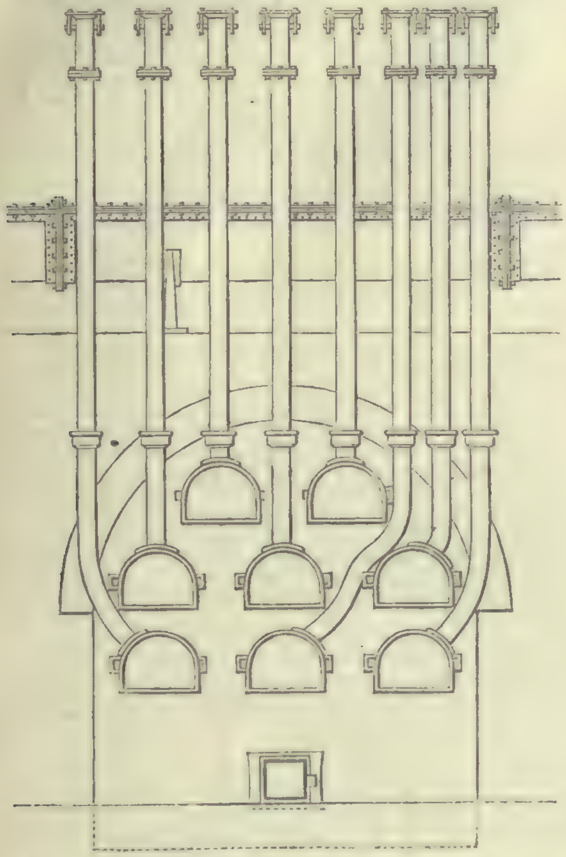






Now the differences we thus find to prevail in the shape, dimensions, and materials of gas retorts, extend likewise to the manner of their arrangement in the same bed, as the assemblage of retorts heated by one furnace is called. According to the size of the locality to be supplied, 1, 2, 3, 5, 7, or even as many as 12 retorts are fixed in the same setting, though it is very questionable whether any real advantage be gained by exceeding the number of 7 or 8. The advantage of placing several retorts in one bed, being only that they require, under such circumstances, less fuel to bring the coal to the required temperature, there must be a point at which the increased cost of labour, from the difficulty of *drawing* (or removing the carbonised coal from the upper retorts) must balance the economy of fuel. Assuming then that seven or eight retorts in a bed are the most convenient and economical arrangement in large works, the setting of the retorts in small works would be regulated on the calculation that each ordinary D retort will yield a fair working result of from 2500 to 2700 cubic feet per day: and the number of such retorts in a bed must be regulated according to the size of the town and its consumption of gas, so as to have the smallest possible number of furnaces alight at the same time. The nature of the fuel burnt under the retorts may modify the ordinary course of proceedings, however, and in some cases the character of the foundations upon which the retort beds are placed may render it unadvisable to concentrate a great weight in one spot.

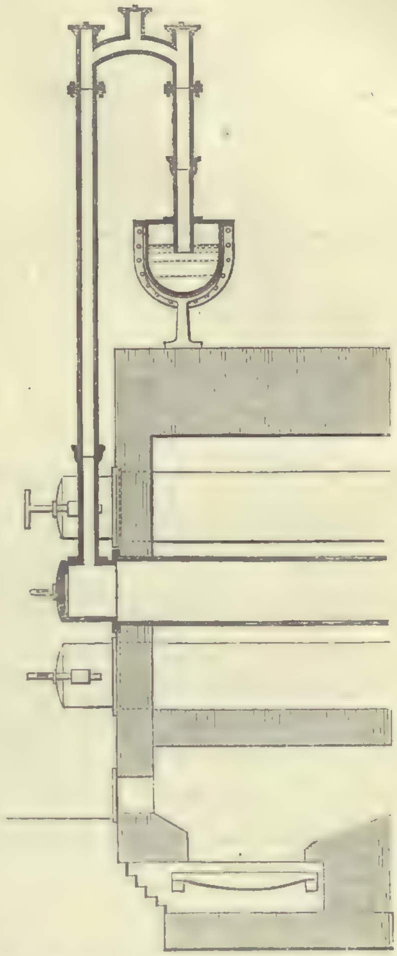
Whatever be the shape of the ordinary retorts (that is to say, of those in which no attempt is made to obtain metallurgic coke), the exposed end of the retort bears a *mouthpiece*, to which is attached the *rising* or *stand-pipe*, or the pipe through which the crude gas passes from the interior of the retort into the *hydraulic main*, to be described hereafter. As this mouthpiece is frequently exposed to severe shocks, it is made of cast iron, even when clay retorts are used; and it bears two ears which receive the ends of the *lids*, or covering-plates, and the *cross-bars* used for fastening the lid (by means of a strong square threaded screw) to the mouthpiece. The imperviousness of the junction of the mouthpieces and lids is, moreover, assisted by covering the bearing surface with a luting composed of the spent lime from the purifiers (when that material is used) mixed with fire-clay. The stand-pipe is usually formed in a separate casting from the mouthpiece, and



it is bolted on to a species of saddle formed to receive it; the diameter at the bottom, in ordinary retorts, being generally about 6 inches, and at the top 4 inches. In such cases the length of the stand-pipe is about 10 feet; but the number of retorts in a bed must naturally affect this dimension. At the top of it there is fitted one end of a short bent pipe, known as the *H-pipe*, or the *bridge-piece*, which by its other end is connected with the *descending pipe*, and by it with the hydraulic main; the lower end of the descending pipe being carried about two or three inches below the surface of the water and tar of the main, and thus converted into a species of hydraulic seal, to prevent the return of the gas to the retort after it has once risen through the water. The H-pipes bear at the top a moveable cup.

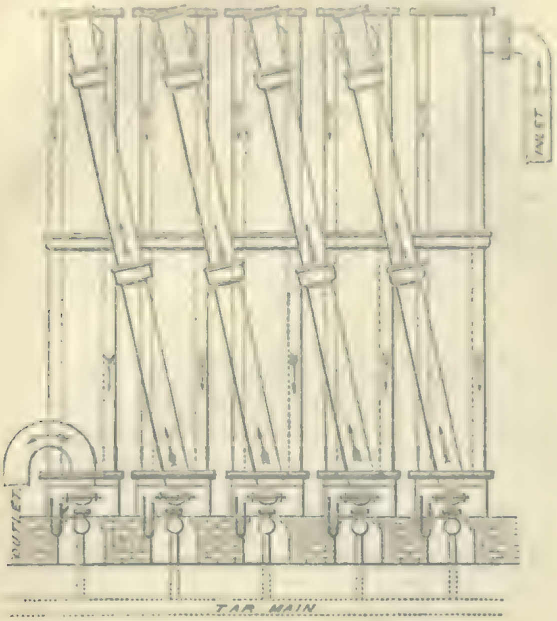
The hydraulic main is a species of iron trough, rather more than half filled with water, which is sometimes carried on columns in front of the mouthpieces of the retorts, but is, generally speaking, placed a little within the line of the retort setting, so as to allow of its being supported from the same. Whether the hydraulic main be within or without the front line of the retort beds, it must run from one end of the retort house to the other; and under any circumstances it must be kept sufficiently high to allow good head-room beneath it, and to remove it from the direct action of the flames which escape when the retorts are being charged. The dimensions of the main must be sufficient to contain the quantity of tar and water which should be able to close the immersed ends of the H-pieces when the mouthpieces of the retorts are opened; for at that period the pressure of the gas into the main will cause the tar to rise in the pipe to a point depending upon the pressure itself. Another condition to be observed in the construction of an hydraulic main is, that the exit pipe should be placed above the surface of the tar, in order to prevent any interference with the passage of the gas to the condensers. A small outlet pipe is inserted at the ends of the main, through which the surplus tar flows into the tar cistern; the lower end of this overflow pipe must be carefully sealed, in order to avoid any escape of gas through it.

It would perhaps be dangerous in a general description of the process of gas-making, to attempt to lay down the laws for the construction and dimensions of the furnaces and flues required for the purpose of heating the retorts to the requisite temperature for the distillation of the coal; because the varieties in the dimensions of the retorts and of the materials employed in their construction, as well as of the fuel used for heating the retorts, render it necessary to introduce many modifications in the furnaces. The object to be attained is, to heat cast-iron retorts to a uniform cherry-red heat, in the interior; or to heat clay retorts to a white heat, with the smallest possible expenditure of fuel; and, after all, much must be left in these matters to the tact and skill of the operative engineer who fixes the work. It is usual, it may be here added, to calculate that, when retorts are heated by the waste coke of the gas factory itself, about from 25 to 35 per cent. of the coke made is burnt under the retorts. Sometimes tar is burnt in the furnaces; but as the local markets for the residual products of gas-making constantly vary, it is not advisable to attempt to discover any general law in respect of the nature of the fuel, any more than it was in the case of the size and details of the furnaces and flues. The mode of charging the retorts is another detail of the service of a retort house in which many differences prevail; for in small country works, where it is important to keep down the outlay for labour, the stoker is made to charge the retorts by means of a shovel; whereas, in large works, the whole of the charge is frequently placed in a *scoop*, and is inserted in the retort at once: the object to be attained in either case being to distribute the coal for distillation in a uniform coat of about 5 inches in thickness all over the bottom of the retort, and to leave the mouth open for the shortest possible time, in order to avoid any unnecessary lowering of the temperature. There are, in fact, few details in the process of gas-making of equal importance to the regulation of the temperature of the retorts, and it is impossible to call the attention of the workmen too forcibly to the subject. If, for instance, the heat be maintained for any length of time at a very high point, the retorts will be burnt out rapidly, and the proper quantity of gas per ton of coal will not be obtained. If, on the other hand, the heat of the retorts be too low, a large quantity of tar will be formed, the quality of the gas will be inferior, and the rate of distillation will be protracted. When the temperature of the retorts is properly regulated, and the quality of the coals used is of an ordinarily good description, it may generally be calculated that a ton of coals will yield between 8700 to 9300 cubic feet, measured by the station-meter before being passed into the gas-holder.



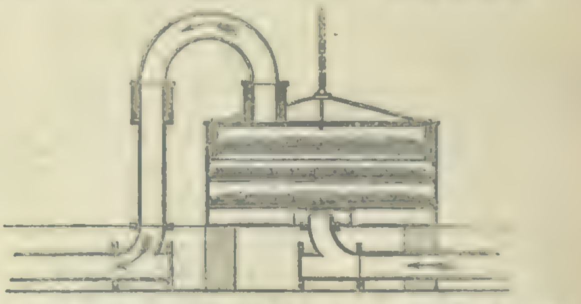
2. From the hydraulic main the gas passes at an average temperature of 120° Fahr. into the *condensers*. The condensers in the best modern works are formed by means of a series of vertical pipes, whose lower ends dip in water for the purpose of arresting the passage of the tar carried over, and which are connected by a second series of inclined pipes passing from the bottom of the first vertical pipe to the top of the second pipe. In its passage through these pipes the gas parts with some portion of its heat by radiation (and therefore the diameter of the vertical pipes should be made as large as possible) until at last, at the final exit pipe, the gas is lowered in temperature to about 60° (but

never below 45°). After leaving the condensers, the gas sometimes passes into the *scrubbers*, which usually consist of a series of shelves covered with screened porous coke; and the gas, passing through these materials, and being in its passage exposed to the action of a stream of water filtering constantly through the coke, parts with the remaining portion of its tar and a considerable portion of the ammonia it holds in solution. In large works, what is called a *washer* is often used instead of a scrubber, and in it the gas is made to pass through a solution of muriate of manganese, whose action upon the ammonia is the same as, or even more effectual than, that of the scrubber. From thence the gas passes into the *purifiers*, where the sulphuretted hydrogen, and many of the remaining ammoniacal elements it may contain, are eliminated, so that on leaving the purifiers the gas is fit to be passed through the *station-meter* into the *gas-holders* in a state adapted for household consumption. As a general rule, the exposed surface of the condensers should be in the proportion of 150 feet superficial to every 1000 feet of gas operated upon; but every description of coal will require a special treatment in this respect; because the more highly bituminous coals, for instance, part with the tarry matters volatilised in the retorts with more difficulty than do the ordinary coals; and it is desirable to retain as much as possible of those matters, provided that they be not exposed to deposition at any time in the course of their passage through the distributing mains.



When the gas leaves the condensers it usually contains impurities, consisting of about 1½ parts of ammonia, 8 parts of sulphuretted hydrogen, and 25 parts of carbonic acid in every 1000 measures of the gas, according to the author of the very remarkable papers on the 'Chemistry of Coal Gas,' inserted in the 2nd and 3rd vols. of the 'Journal of Gas Lighting.' For the purpose of removing these impurities it would appear that the most theoretically perfect course would be to pass the gas, firstly, through either the sulphate, or the muriate of lime, and then to pass it through the pure hydrated lime in powder. It happens, however, that some of the impurities which are retained by these forms of lime, namely, the hydro-sulphate of ammonia, and the hydro-sulphate of lime, are either extremely volatile, or are susceptible of decomposition on exposure to the air; and under such circumstances their removal from the purifiers, when the lime itself has been saturated, gives rise to so great a nuisance that in crowded districts, or in the centre of towns, it is necessary to employ some other material than lime as the basis of the purification. It is for this purpose that metallic salts have lately been introduced; and in some of the most scientifically managed works (as at Liverpool for instance), the process adopted within a very recent period, has been described as being as follows: "Common green copperas (sulphate of iron) is put into a mill, a little water being added to make it into a pasty mass. Slaked lime is then added, in the proportions of one part of lime to two of copperas, with water sufficient to make the whole, when ground together, of the consistency of a stiff paste. In this state it is removed, and cut into pieces with a spade, and as it dries it forms a powder which consists of sulphate of lime and hydrated sesquinoxide of iron. The powder, after being sifted is put into the purifier, where the oxide of iron becomes reconverted into sulphuret of iron; and that again by exposure to the air becomes reconverted into oxide of iron with a deposition of sulphur in the mass. This process is repeated about 28 times, and then it is found, that owing to the accumulation of sulphur, the same material cannot again be put into the purifier. In this state the material is roasted in an oven, the sulphur being in the first instance distilled from the mass, and collected in a separate form, and during the roasting process, the iron becomes red hot, and is rendered anhydrous. When taken out of the ovens the iron is thrown into open yards to cool; and is then moistened with water, in order to reconvert it into the hydrous oxide, and again put into the purifiers to commence a fresh succession of repeated actions." In the majority of the London works saw dust is mixed with the oxide of iron to increase its active surface; and in some cases the gas is made to pass through the muriate of manganese *before* passing through the iron, whilst in others it is passed through dry lime purifiers *after* leaving the iron, because the action of the latter material is not sufficiently energetic to remove all the ammonia, nor does it materially affect the carbonic acid, in its various forms of the gas.

The lime used for the purification of gas should be of the purest and richest description, such in fact as would be obtained by the calcination of chalk, or of crystalline carbonates of lime, and which expands in volume very considerably when slaked. It should be kept in store in lumps, but ground before being used, and mixed with a sufficient quantity of water to bring it into a stiff plastic state; and in that state it must be spread upon the screens of the purifiers in an even sheet of, *at the most*, 2½ inches in thickness. The successful working of the lime depends, it may be observed, on the evenness of the layer; but the most economical condition for its use is that it should expose a large surface to the gas passing through. Generally speaking, it is calculated that one bushel of ground dry lime will when slaked, spread over a surface of 25 superficial feet, and suffice for the purification of 10,000 cubic feet of Newcastle coal gas. In the oxide of iron purification, a greater surface is required than when lime only is used; but the proportion usually adopted is to make the area of the purifiers such that they should present a surface of one superficial foot to every 150 cubic feet of gas they are intended to pass: and the diameter of the connecting pipes is made in inches, equal to the square root of the area of the purifiers in feet superficial. The use of wet lime purifiers is now so universally abandoned, that it is not worth while to enter into a description of the mode of forming or of working them.

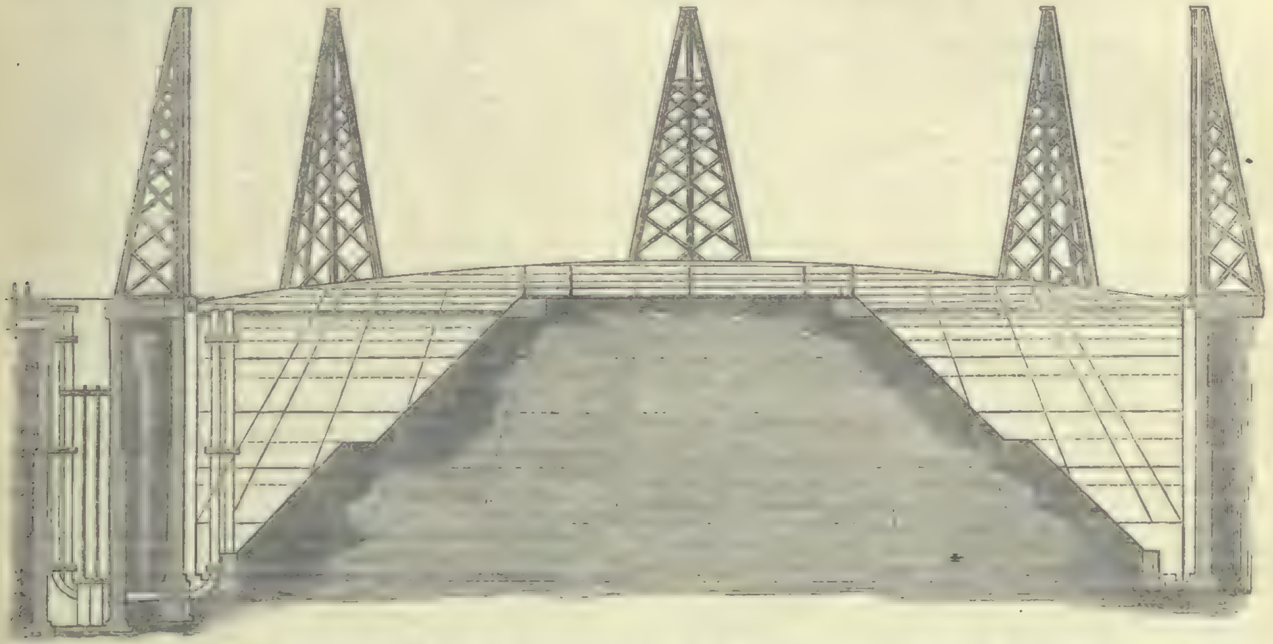


One of the most important duties of the manager of a gas factory is to ascertain that his purifiers operate successfully, and for this purpose he should frequently test the gas by means of paper, prepared by being steeped in a solution of acetate of lead in distilled water, one of the best tests for sulphuretted hydrogen. The papers should not be changed in colour by contact with the gas in the last of the series of purifiers. Sometimes papers steeped in a solution of the nitrate of silver are used as tests of the purity of gas from sulphuretted hydrogen. Test papers of litmus are used to detect ammonia, or carbonic oxide.

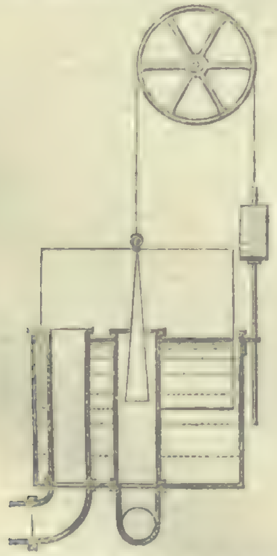
It may be as well here to add that the order in which the gas is made to pass through the purifier and the scrubber, is frequently the reverse of the one described above; and in small works the use of the scrubber is often entirely dispensed with.

3. The first operation which it is desirable to adopt in the storeage of gas, is to pass it through the station meter, in order to be able to control the working of the retort house, and to check roughly the consumption in the mains and the private distribution. For the former purpose it is necessary that the wheel-work of the meter should carry a "tell-tale," by means of which the passage of the gas is recorded in such a manner as to allow the rate of working, hour by hour, to be identified. The value of the station meter, as a check upon the actual consumption, must vary in a marked degree with the circumstances of the localities, and the mode of manufacture; for the rate of leakage, and the amount of condensation, which may take place after the gas should have passed the meter, differ in almost every town. It is, however, by no means rare to find that the loss, known in gas-working accounts, under the name of "unaccounted for gas," amounts to as much as 20 per cent. of the total quantity passing through the station meter; and the efforts of the superintendent must be earnestly directed to reducing it to a minimum. Even if a portion of the loss be attributable to the condensation of the holder and pipes, it argues an unsatisfactory state of working; for the temperature of the gas ought to have been lowered, before it was passed into the purifiers, to such a point as to render any subsequent condensation impossible unless in intensely cold weather.

The gas holder is a large wrought-iron vessel, either of one or more lifts, according to the nature of the locality (but wherever it is possible, of only one), which should be made large enough to hold one day's normal consumption (at the period of the shortest days) of gas. The holder is, in fact, an inverted cup, working in water, and in a close brick or iron tank, and rising by the elasticity of the gas entering through the inlet pipes; the discharge taking place through the exit pipes to the *governor*, by the mere weight of the holder. The pressure required to raise a holder is ascertained by the formula $p = \frac{w}{a\,5{\cdot}2}$ in which p = the pressure in inches (of a column of water); w = the weight of the holder in pounds; and a = the area of the water surface in feet; the constant 5·2 is the weight in pounds of a superficial foot of water one inch thick. The effluent pressure is found by the formula $p = \frac{547\,w}{d^2}$, in which p and w represent as before the pressure and weight, and d = the diameter of the holder in feet; the constant 547 representing the weight of a column of water in inches, of the area of the holder. Strictly speaking it would be necessary to allow for the levity of the gas, and for loss of weight in the sides of the holder as it may descend; but these considerations are so habitually neglected in practice as to justify the reference of the practical student to Clegg's 'Practical Treatise on the Manufacture of Coal Gas,' for further details.



The *Governor* is a machine for the purpose of regulating the pressure upon the outlet pipe, according to the hours of the day, and the draught upon the mains; and one of these machines must be placed at least upon each leading main of a town distribution, large or small. There are numberless patents for the construction of governors; but practically the system described by Clegg is the best, and therefore a sketch of it is appended. Its action and principles are described in detail in the work above mentioned.



Attached to the outlet-pipe of the governor there should be placed a *self-registering pressure gauge*, in order to control the operations of the men charged with the regularisation of the pressure; and one or more ordinary pressure gauges should be placed upon the leading main, for occasional observations. The self-registering gauge invented by the late Alexander Wright is one of the best, if not actually the best, instrument of this description.

4. The distribution of gas is effected by means of cast-iron mains, in all cases where their diameter exceeds 2 inches; and indeed in all cases where the pipes would be exposed to the action of moisture it is preferable to employ cast, rather than wrought, iron for street mains, even at the risk of employing larger ones than would theoretically be required. The service pipes, or those through which the gas is led into the consumer's meters, are, however, almost always of wrought iron when the diameter exceeds half an inch; below that dimension they are either made of tin or of composition, on account of the greater facility with which they can be bent to the abrupt curves frequently required in house fittings. The joints of the cast-iron pipes are usually of the description known as *socket-joints;* those of the wrought-iron pipes are of the description known as *screw-couplings;* whilst those of the smaller pipes are made by soldering in the ordinary way. The wrought-iron services are tapped and screwed into the cast-iron mains, and the composition pipes are joined to the wrought-iron ones by means of a brass screwed end, which is run upon the composition and fits into a female screw on the service pipe.

Before describing the laws which are now admitted with respect to the flow of gas in pipes, it may perhaps be advisable to make some remarks upon the quality, and the mode of manufacture, of gas mains; because the economical results of any operation of this description must, after all, greatly depend upon the manner in which those mains discharge their functions. It has been stated above, that the "unaccounted for gas" frequently amounts to as much as 20 per cent. of the total quantity made; and as very probably one-half or one-third of this loss is to be attributed to the permeation of the gas through the mains, it becomes a matter of serious importance to prevent such a loss. The principal difficulty lies in this case, as in so many other practical ones, in the prices of the various goods considered; and gas companies are too often tempted to use cheap porous pipes, obtained from first runnings, rather than incur the expense of sound second runnings. This is a very mistaken economy; and it may be laid down as a rule in these matters, that no gas mains should be allowed to be made in any works where a blast furnace exists; all mains should, in fact, be made from second runnings, and under the immediate inspection of the engineer of the gas-works; and they should all be cast vertically, with a requisite length of feeder to ensure the solidity of the metal. The very conditions of manufacture of wrought-iron pipes render them less likely to be porous than cast-iron ones frequently are; but the cheap composition pipes are so fearfully defective, that the greatest precautions should be taken in their application, and none but the most respectable and most experienced gas-fitters should be employed. No doubt many of the sad accidents recorded, of explosions in houses, are to be attributed to the use of inferior composition service pipes for the distribution of gas.

In arranging the dimensions of the mains of a gas distribution it is to be observed, first, that there is an economy of working expenses, in making the mains rather larger than would theoretically be required to deliver the quantity of gas they are originally intended to supply; because, in such a case, the gas might be made to work under a diminished pressure, and thus the leakage would be diminished. The diameters of the mains are to be ascertained by dividing the district to be supplied into certain sub-districts, according to their relative consumption, and then applying the formulæ $v = \sqrt{2g\frac{p}{s}}$; and $p = \frac{s}{2g}v^2$; the former for the purpose of determining the velocity of the gas due to a certain pressure; and the latter, the pressure for a given velocity. In these formulæ, $p =$ the pressure; $v =$ the velocity; $g =$ the force of gravity $= 32{\cdot}19$; $s =$ the weight of a cubic foot of the gas in pounds; but no attention is paid to the retarding effects of friction in the mains, or to those produced by bends, or other incidental causes. Taking the friction alone into account, it has been considered that the total pressure at the end of a pipe may be represented by the formula $p = \left(\frac{1}{2g} + M l \frac{c}{a}\right) s v^2$; in which the new terms, $M =$ a coefficient determined by experience to be $= {\cdot}00011$; $l =$ the length of the main; $c =$ the inner circumference of the pipe; and $a =$ its area. Clegg enters at length into the mathematical reasoning on this subject; and the reader is referred to his work for further details upon it; but it may suffice for present purposes to state that he finally quotes, for ascertaining practically the quantity discharged by a pipe, the formula $Q = 1350\, d^2 \sqrt{\frac{hd}{sl}}$; in which $Q =$ the quantity sought; $d =$ the diameter of the pipe in inches; $h =$ the working pressure in inches; $l =$ the length of the pipe in yards; and $s =$ the specific gravity of the gas compared to that of atmospheric air as unity. Provided the radius of the bends upon a length of main be large, there is little necessity for taking them into account; and indeed the simple precaution of making the diameter of the pipe rather larger than would theoretically be required, would obviate any necessity for so doing.

Under any circumstances, when a town is characterised by great irregularities of level, it is desirable to insert, upon the leading mains, species of receivers provided with governors at the points where the marked changes of level occur. When, on the contrary, the town is (like those of Holland) nearly upon a dead level, and close to the water-line of the district, it becomes necessary to insert numerous syphons in order to relieve the mains of the tar and other liquids which may find their way into those mains; and in towns of this character it is desirable to give an inclination of about 1 in 600 towards the syphons. It is of course necessary to maintain an efficient seal in the syphon box, and to provide a small discharge pipe to draw off any excess of tar or water. Another detail of pipe laying, which requires to be considered, is the position of the valves to be placed for the purpose of shutting off the gas during the repairs of the mains. These valves must be placed so as to interfere with the service in the smallest possible degree; but no definite rule can be laid down in any of the matters of local detail.

In laying the pipes great care should be exercised in forming a regular and incompressible bed, and in rigidly adhering to the rates of inclination prescribed. As a general rule, the pipes for conveying gas may be laid at the depth of 2 feet from the surface; but of course the latitude of the locality considered may render it advisable to modify this law. If any water-pipes should be laid in the same street as the gas-pipes, the latter must be kept as far from them as possible, and under any circumstances they must be placed *above* the water-pipes; serious accidents have indeed occurred from the neglect of these precautions, for occasionally the gas has found its way into water-pipes, by the singular action known by the names of endosmose and exosmose, and explosions have taken place at the outlet. The greatest possible care should be taken in laying the mains to ensure the tightness of the joints, as it is at such places that the gas most commonly escapes.

The following tables may be considered to represent, first, the dimensions and weights of gas-pipes of various diameters; and secondly, the quantity of gas which pipes of the respective diameters will deliver, under ordinary circumstances, with the pressure of 1 inch.

Table I. Dimensions and Weights of Pipes.

Column No. 1 represents the diameter in inches; No. 2 the number of belts in the length of pipe; No. 3, the thickness; No. 4, the mean weight of each pipe; No. 5, the tolerated deviation of weight of each pipe; No. 6, the net length of the pipes; No. 7, the ordinary price for laying and jointing, without earthworks, calculated per yard lineal.

1.	2.	3.	4.			5.	6.	7.

2	2000	8	32,000		

With respect to the consumers' fittings, it may be as well to observe that the public lamps in streets should be made to consume at the rate of 5 feet per hour on the average of the night; and that gas companies would find it desirable to use regulators upon these lamps, both for the sake of checking the waste of gas, and of improving the light from them. As a rule, the lamp-posts in the streets of populous towns should be placed alternately on either side of the street, and at a distance of from 22 to 30 yards (measured on the axis); though in the less frequented districts, the distance asunder of the posts (measured as before) may be carried, without inconvenience, even to 60 yards. The height of the flame in the lamps should be about 12 feet above the ground line.

In private houses, the character of the fittings, and the quantity of gas burnt to light a given space, depend so much upon the taste of the consumer, and the details of the burners are exposed to such constant changes from the whims and fancies of the gas fitters, that it is impossible to lay down any positive rules with respect to them, other than a few general ones derived from the ordinary principles of lighting. Thus, it is preferable to distribute the light of a room by means of a number of burners consuming small quantities of gas, rather than to concentrate it in one central burner consuming a large quantity; because the effect of artificial light diminishes in the ratio nearly of the square of the distance from its source. Of the various kinds of burners used, the ordinary Argand burner seems, quantity of gas for quantity, to be the most convenient and the most economical. The bats-wing burners are the next in the order of relative economy; and the fish-tail burners the last. The so-called solar lamps are admirably adapted for lighting large rooms, wherein it may not be desirable to distribute the sources of light, or wherein it is desired to establish an active upward ventilation; but they are expensive, and on account of the heat they evolve, they render it necessary to adopt certain precautions in the construction of the building.

Whatever description of burner be used, attention must be paid to regulate the escape of the gas, in such wise as to prevent its issuing with too great a pressure, because in the latter case a large portion of the gas would only be partially burnt, and would thus cause much smoke. As to the asserted injury to furniture, books, &c., from the use of gas in dwellings, it is curious that in an old French work, published at Lausanne in 1770, precisely the same accusation was brought against the use of coal in fire-places as is now brought against gas; and the inference to be drawn from this tale is, that certainly the latter cannot be at fault, whilst probably there may be exaggeration in both cases. The heat of gas is also at times objected to, but if the same amount of light were obtained by any other method of artificial lighting, even greater heat would be evolved; and in either case attention is required to ensure an efficient ventilation. This is the more necessary from the fact, that by whatever means artificial light is obtained, its brilliance can only be secured by the consumption of oxygen; and therefore it is essential that an ample supply of fresh air should be introduced to maintain the combustion, if for no other purpose.

A great deal of attention has lately been directed to the question of gas-meters, and a special act of parliament has been passed (22 & 23 Vict. c. 66) to regulate them. It may suffice here to say that meters are of two sorts, dry or wet; and that the latter work satisfactorily, if kept properly filled, for a longer period than the former. Both of them, however, must now be made with such accuracy that they should only have a range of error of 2 per cent. above, or below, the mathematical quantity indicated: and if the best compensating meters be used, there need be no fear of any subsequent tampering on the part of the gas companies. It is usually calculated that the consumer's meter causes a loss of pressure from its friction equivalent to about one-tenth of an inch. [See Meters, Water and Gas.]

5. The accessory buildings required for a gas factory, in addition to those required for the station meter and the governor, are merely those required for storing the coal, for receiving the fresh and the spent lime, and the coke and tar for sale; and occasionally some rooms for experiments upon the quality, and the chemical composition, of the gas; though in small works these rooms are but rarely required. If the works should be placed at any distance from the source of supply of fuel, the size of the coal sheds should be made sufficient to contain about three months' consumption. The coke shed need not be large, for it is decidedly the interest of the maker to sell it at once; and the stock of tar should at all times be kept as low as possible, on account of its inflammable nature. The lime-sheds also do not require any great capacity, but they should be weather-proof.

The dimensions of the chimney must be calculated according to the ordinary laws of the motion of heated elastic fluids, so as to ensure an efficient draught under the retorts without wasting fuel. Lofty chimneys are usually mistakes in gas-works, and it is a common maxim amongst practical engineers, that the profits are in the inverse ratio of the height of a chimney. In fact, in an open country a height of 45 or 50 feet is sufficient for a chimney serving for four beds of five retorts each. And here, perhaps, it may be as well to observe that it is in executing the foundations for the retort beds, the chimney stalk, and the gas holder, that the greatest difficulties arise in practice; and they require all the attention and the skill of the engineer.

In most country factories residences are provided for the workmen who are constantly employed; a small office and store room is constructed; and rooms are provided to receive a stock of meters, and of fittings; for the country companies in many cases are obliged to retain this branch of trade in their own hands, in order to secure its proper execution. Sometimes a board-room, and a meeting-room, are also provided.

The operation of testing the quality of a gas, with respect to its illuminating properties, is an operation of so delicate and so important a nature, that it may be desirable to dwell a little upon this part of the science of Photometry, at least so far as may be necessary to explain its ordinary application in commercial affairs.

The principles upon which the photometers in general use are constructed, are based upon the law that "the power of a luminous body to light a given space is directly proportional to the intensity of the light itself, and inversely proportional to the square of the distance of the point of observation from it;" and its application is obtained by causing the two sources of light it may be desired to compare, to shine upon the respective sides of a thin and partially translucent body. When the illumination of the exposed surfaces of the latter is equal, that is to say, when neither of these faces possesses a greater degree of luminosity than the other, the illuminating powers of the sources of light with respect to the interposed body are said to balance one another. If then one of the sources of light be a lamp, or candle, possessing known illuminating properties, it is easy to calculate the relative value of the other, in terms of the power of the standard, according to their respective distances from the interposed object. The difficulty, of course, lies in the selection of an invariable standard for this purpose, and the choice of gas engineers varies between wax and spermaceti candles, or the Carcel lamp. In England, the standard usually adopted is the spermaceti candle, burning 120 grains per hour; in France, the standard is frequently the Carcel lamp, burning 42 grammes (2·4 oz.) of rape oil per hour; and when the light of either of those illuminating bodies is to be compared with gas, the latter must be admitted in certain definite quantities (usually about 5 cubic feet per hour), and under a carefully regulated pressure.

The thin partially illuminated screen above referred to, in the Bunsen photometer (the one usually adopted with various modifications in England), presents a surface which is white, but nearly opaque on the circumference, and perfectly translucent in the centre. The preparation of this disk is a matter of great delicacy, for the translucent part should differ as little as possible in colour from the rest of the surface, when the illumination of its sides is equal. Dr. Fyfe, and the majority of English makers of photometers, use cream-coloured writing-paper for the screen, and they mark the translucent centre covering it with a solution of spermaceti in oil of naphtha equally diffused over its surface; the diameter of this translucent centre is usually about the same as that of a half-crown piece. In the photometers made by the late Alexander Wright and his successors, the screen was placed in the middle of a cylindrical shade, blackened on the inside: and it worked upon a bar graduated so as to express at once the value in candles and decimal parts of candles, of the legal standard, of the light experimented upon. Great care ought to be taken to exclude any extraneous rays of light derived from reflection from the sides of the room, or from the surface of the graduated bar; so that, in fact, none but the direct rays from the respective sources of light should be allowed to impinge upon the screen. The length of the bar in Wright's photometer is about 100 inches; in Church & Mann's photometer it is considerably less; and, indeed, for some reasons the latter instrument seems to be the most convenient one of its kind.

It is curious that notwithstanding the importance of the operations of photometry, in many cases of disputed contract, no attempt has been made to ascertain the limits of what M. Quetelet calls "the personal equation of observation" in them. The powers of every individual to appreciate degrees of luminosity differ, more or less; and the singular discrepancies in the results of the recorded observations on this subject may be to some extent accounted for on this ground.

A series of tables of the illuminating powers of the gas obtained from the coals generally used in England, will be found in the new edition of Clegg; a book which, by the way, entirely supersedes all other works upon the subject. In the same work there are some equally interesting tables of the composition of the various coals themselves, and a valuable chapter upon the modes of dealing with the residual products of the manufacture of gas. The reader is, therefore, referred to Clegg's 'Practical Treatise on the Manufacture of Coal Gas,' 1859; to D'Hurcourt's 'Traité de l'Eclairage au Gaz,' 1845; Peckston, 'On the Theory and Practice of Gas Lighting,' 1823; and Accum's 'Practical Treatise on Gas Light,' 1815. In the 'Journal of Gas Lighting,' a vast amount of useful practical and theoretical information may be found on this subject; and likewise in the 'Practical Mechanics' Journal.' The latter, particularly, contains some elaborate articles on the various systems introduced by Mr. Bowyer, of St. Neot's, for the purpose of applying gas on a suitable scale for the economical lighting of small towns, and even of private houses. Some notion of the national importance of the gas industry may be formed from the fact that there are in existence in the United Kingdoms about 1000 gas companies, and that it is able to support special journals, not only in England, but also in France, Germany, and the United States.

GASES, COLLECTION OF. The collection and preservation of gases form a class of chemical operations so essentially distinct from those employed in manipulations with the other two forms of matter, that it will be useful to describe them in a separate article.

The chief difficulty to be overcome in manipulations with gases is their diffusibility or tendency to mix with atmospheric air, a property which gases possess to such an extent that comparatively few substances are capable of entirely resisting the passage of gaseous matter through their pores. This diffusibility renders the collection of gases by displacing one gas, contained in any vessel, by means of another, always an imperfect and frequently an impracticable operation; nevertheless, where the two gases differ considerably in specific gravity, and when absolute purity is not required, this process may sometimes be resorted to with advantage.

Collection of gases by gaseous displacement.—In this process the gas displaced is always atmospheric air, and in order to apply it successfully it is necessary that the gas should be generated in a copious stream, and it is also desirable that its specific gravity should differ considerably from that of the atmosphere. Tall and narrow glass cylinders or bottles are best adapted for this purpose. If the gas to be collected be heavier than air, the jar in which it is received must be placed with its mouth upwards, and the tube conveying the gas must terminate at or near the bottom of the jar, as in *fig.* 1. If, on the other hand, the gas be lighter than air, the jar must be inverted, and the gas delivery tube must reach as before to the closed end of the cylinder, as in *fig.* 2.

Fig. 1.

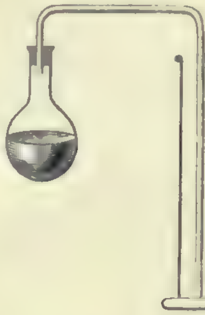

Fig. 2.

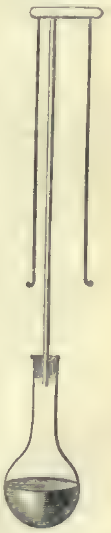

Fig. 3.

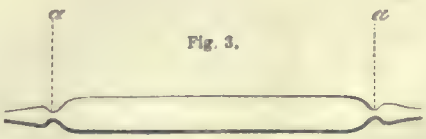
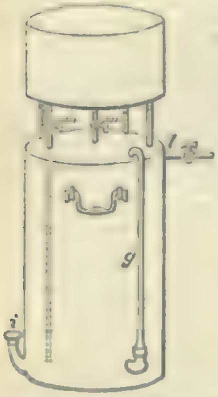


A modification of this method is frequently employed in the collection of gases for analyses, where a high degree of purity is indispensable. The gas-delivery tube is connected with a glass tube or series of tubes drawn out at both ends, as shown in *fig.* 3, and the current is continued until the last traces of air are expelled, an operation which is facilitated by connecting the extremity where the gas is issuing with a long caoutchouc tube, which prevents the retrogression of air by diffusion. When the current has been continued for a sufficient length of time it is interrupted, and the tube is rapidly sealed up hermetically, by the application of a mouth-blowpipe flame to the narrowest portions, *a a*.

Collection of gases by displacement of water.—This is by far the most common method in use, although without great care and the employment of recently boiled water it is impossible to preserve the gas free from admixture with air, because all gases being more or less soluble in water, a transference of the gas into the air, and *vice versâ*, is constantly taking place through the confining liquid. The most simple mode of collecting gases by this process consists in filling a glass jar, such as that shown in *fig.* 1, with water, inverting it on the shelf of a pneumatic trough, and then bringing the extremity of the gas delivery tube beneath the mouth of the jar; the gas then bubbles through the water, ascends into the upper part of the jar, and displaces the water with which the latter was previously filled.

Larger quantities of gases are collected in *gasholders*, or *gasometers*, by this method. *Fig.* 4 represents the gasholder most generally employed for experimental purposes. It consists of a cylindrical copper vessel, closed at top and bottom, and at about 6 inches above it a second shorter cylinder, open at top, is fixed upon suitable supports. The two cylinders are connected by means of two tubes, *m*, *n*, furnished with stopcocks; *m* passes nearly to the bottom of the lower cylinder, whilst *n* terminates under its cover. At *l* there is also a stopcock and short tube, and at *i* there is a larger orifice which can be securely closed by means of a screw-plug.

Fig. 4.



To use this gasholder, the plug *i* must be screwed into its place, all the stopcocks opened, and water poured into the upper cylinder. The water will descend through the tube *m*, and expel the air from the lower cylinder through the stopcocks, *n*, *l*; when water issues from the latter, the lower cylinder is filled: *m*, *n*, and *l* must now be closed, and the screw-plug, *i*, being removed, the apparatus is ready for the collection of gas. The tube conveying the latter must be inserted into *i*; the bubbles will now ascend to the upper part of the cylinder, displacing a corresponding volume of water, which will flow out of *i*. The quantity of gas collected is conveniently seen by means of the glass gauge-tube, *g*. When the necessary amount of gas has thus been received in the holder, the delivery tube is removed from *i*, and the screw-plug replaced. The gas may at any time be expelled from this holder for experimental purposes, either through the tube *n* into jars filled with water and inverted over its orifice, or through *l* in a continuous stream, which is often desirable. The expulsion of the gas through either of these orifices is effected by opening the stopcock, *m*, and keeping the upper cylinder supplied with water. It is scarcely necessary to remark that such gases only as are sparingly soluble in water can be collected by this process.

Collection of gases by displacement of mercury.—This is by far the best process for the collection of gases in a state of perfect purity, although it is less frequently employed than the other two processes, owing to the difficulty of manipulating with a heavy fluid like mercury. The process exactly resembles in principle the collection by displacement of water, but owing to the high specific gravity of mercury, vessels of small size only can be used; hence glass tubes of a diameter varying from half an inch to 1¼ inch are generally employed. Care must be taken not to allow the gas-delivery tube to dip too deep into the metal, otherwise the great pressure upon the gas-generating apparatus may endanger the tightness of the joints. This method may be applied to all gases except chlorine and hydrofluoric acid.

In addition to these methods of collection, many gases may be conveniently stored up in caoutchouc or mackintosh bags, when purity is not of importance; but they should not be retained in such bags more than 48 hours, otherwise they become mixed with considerable quantities of air. Care should be taken not to collect coal-gas in caoutchouc, as the latter becomes softened and partially dissolved.

GASES, LIQUEFACTION OF. We are indebted chiefly to Professor Faraday for our knowledge of liquified and solidified gases. The method which he employed consisted in combining the condensing power of mechanical compression with that of very considerable depression of temperature. The first object was attained by the successive action of two air-pumps; the first having a piston of one inch in diameter, by which the gas to be condensed was forced into the cylinder of the second pump, the diameter of whose piston was only half an inch. The tubes into which the air, thus further condensed, was made to pass, were of green bottle-glass, from one-sixth to one-quarter of an inch in external diameter, and had a curvature at one portion of their length adapted to immersion in a cooling mixture: they were provided with suitable stopcocks, screws, connecting pieces, and terminal caps, sufficiently air-tight to sustain a pressure of fifty atmospheres. Cold was applied to the curved portions of the tube by their immersion in a bath of Thilorier's mixture of solid carbonic acid and ether. The degree of cold thus produced, when the mixture was surrounded by the air, was —106° Fahr., by an alcohol thermometer. But on placing the mixture under an air-pump, and removing the atmospheric pressure, leaving only that of the vapour of carbonic acid, which amounted only to one twenty-fourth of the former (that is, to the pressure of a column of 1·2 inch of mercury), the thermometer indicated 166° below zero. In this state the ether was very fluid, and the bath could be kept in good order for a quarter of an hour at a time. Mr. Faraday found that there were many gases which, on being subjected to cold of this extreme intensity, condensed into liquids, even without a greater condensation than that arising from the ordinary atmospheric pressure, and they could then be preserved, sealed up in glass tubes in this liquid state. Such was the case with chlorine, cyanogen, ammonia, sulphuretted hydrogen, arseniuretted hydrogen, hydriodic acid, hydrobromic acid, carbonic acid, and euchlorine. With respect to some other gases, such as nitric oxide, fluoride of silicon, and olefiant gas, it was difficult to retain them for any length of time in the tubes, in consequence of the chemical action they exerted on the cements used in the joinings of caps, and other parts of the apparatus. Hydriodic and hydrobromic acids could be obtained either in a solid or liquid state. Hydrochloric acid gas did not freeze at the lowest temperature to which it could be subjected. Sulphurous acid froze into transparent and colourless crystals, of greater specific gravity than the liquid out of which they were formed. Sulphuretted hydrogen solidified in masses of confused crystals of a white colour, at a temperature —122° Fahr. Euchlorine was easily converted from the gaseous state into a solid crystalline body, which by a slight increase of temperature melted into an orange red fluid. Nitrous oxide was obtained solid at the temperature of the carbonic acid bath *in vacuo*, and then appeared as a beautifully clear and colourless crystalline body. Mr. Faraday conceives that in this state it might, in certain cases, be substituted with advantage for carbonic acid in frigorific processes, for arriving at degrees of cold far below those hitherto attained by the employment of the latter substance. Ammonia was obtained in the state of solid white crystals, and retained this form at a temperature of —103°. The following liquids could not be made to freeze at —166°: chlorine, ether, alcohol, bisulphide of carbon, caoutchoucin, camphor, and rectified oil of turpentine.

The following table, chiefly from Miller's 'Elements of Chemistry,' shows the points of liquefaction and solidification of various gases:—

Names of Gases.	Temperature of Solidification.	Pressure in Atmospheres required for Liquefaction.		
		At 32° F.	At 60° F.	° F.
Sulphurous acid . .	—105	1·53	2·54	5·16 at 100°
Cyanogen. . . .	— 30	2·37		4·00 at 63°
Hydriodic acid . .	— 60	3·97	5·86	
Ammonia . . .	—103	4·40	6·90	10·00 at 83°
Sulphuretted hydrogen .	—122	10·00		14·60 at 52°
Protoxide of nitrogen .	—150	32·00		38·40 at 35°
Carbonic acid . .	— 70	38·50		
Euchlorine . . .	— 75			
Hydrobromic acid .	—124			
Fluoride of silicon . .	—220			
Chlorine . . .		8·95	13·19	
Arseniuretted hydrogen				1·00 at —40°
Olefiant gas . . .				26·90 at 0°
Ethyl				2·25 at 37·5°
Fluoride of boron . .				11·54 at —62°
Hydrochloric acid .		26·20		40·00 at 50°

Hydrogen, nitrogen, carbonic oxide, and nitric oxide, have been submitted to pressures of upwards of 800 atmospheres without exhibiting signs of liquefaction.

GASHOLDER or GASOMETER. [GAS, MANUFACTURE OF.]

GASOMETER. [GASES, COLLECTION OF.]

GASOMETRIC ANALYSIS. *Gas analysis. Eudiometrical analysis. Eudiometry.* This branch of chemical analysis originated in the attempts of Fontana, Landriani, Scheele, Priestley, Gay Lussac, and others, to determine the volume of oxygen in samples of atmospheric air taken from various localities. The imperfect methods then used led these observers to believe that there was considerable difference in the per-centage of oxygen contained in the air resting over different portions of the earth's surface, and it was imagined that these differences were closely connected with the unhealthiness or salubrity of various places. Hence the name *eudiometer* (from *εὔδιος* and *μετρεῖν*, measurer of the goodness of air) was given to the instrument used for these determinations.

The principle upon which the use of the eudiometer was made to depend, so far as atmospheric air and oxygen gas are concerned, was that of exposing them to the action of some substance, whether solid, fluid, or gaseous, which, on account of its affinity for oxygen, combined with the latter, leaving the gases with which it was mixed unacted upon.

The eudiometer invented by Dr. Priestley arose from, and was connected with, his great discovery of oxygen gas and the fact which he ascertained of its absorption by another gas, which he called nitrous air, since called deutoxide or binoxide of nitrogen, or nitric oxide gas.

This gas may be considered as nitric acid deprived of a large portion of its oxygen, which is effected by dissolving a metal in it, as, for example, copper, silver, or mercury; and of these the last mentioned yields the gas in the greatest purity. The nitric oxide thus obtained being disposed to regain the oxygen which the metal has taken from it, absorbs it with great facility from all such gaseous mixtures as contain it; the evidences of its action are the formation of a red vapour, condensation of volume, and the reproduction of one of the acids of nitrogen; and the quantity of oxygen absorbed is determined by the degree of condensation which is produced by its action.

Dr. Priestley's method was extremely simple: he took a phial capable of holding about an ounce of water, filled it with water, and displaced the latter with atmospheric air, or with the gaseous mixture to be examined; the volume of this being noted, it was transferred, over water, into an air-jar about an inch and a half in diameter. An equal volume of nitric oxide was added to it, and they remained together for about two minutes: if the diminution was very considerable, another volume of nitric oxide was added. When this part of the process was over, the gas was transferred to a glass tube about two feet long, one-third of an inch in diameter, and graduated into 10ths and 100ths. After noting the volume of the gas, the result was expressed in measures and decimal parts; thus, when equal volumes of common air and nitric oxide were mixed, and they afterwards occupied the space of one volume and two-tenths, Dr. Priestley, in speaking of the air so tried, said the measures of the test were 1·2 or the standard of the air was 1·2. Owing to the formation of several compounds of nitrogen and oxygen in this process it is now known to be entirely unworthy of confidence.

The eudiometer next to be mentioned is that invented by Scheele, which was probably the first proposed after Dr. Priestley's. This was a graduated glass tube containing a certain volume of air, which was exposed to a mixture of sulphur and iron-filings made into a paste with water. Although the oxygen was absorbed and the nitrogen left by this operation, yet the process was not to be relied upon; for, by the formation of sulphuric acid, which occurred by the oxidisement of the sulphur, the iron was acted upon, and water being decomposed, its hydrogen was evolved, and interfered with the results of the operation.

This plan, however imperfect, had the merit of simplicity; for the quantity of oxygen absorbed was determined at once by deducting the volume of the residual gas from that of the whole quantity submitted to experiment.

De Marté, instead of using sulphur and iron, employed a solution of sulphuret of potassium, prepared by dissolving sulphur in a solution of potash. It is stated that this solution when newly prepared absorbs a small portion of nitrogen; but the fallacy arising from this source is partially obviated by agitating the solution for a short time with a little atmospheric air previously to using it, by which it is saturated with nitrogen. A tube divided into 100 parts and immersed in the solution is sufficient for the use of it.

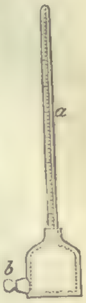
Guyton also employed sulphuret of potassium in his eudiometer, but he used it in a solid state, and applied heat to expedite its action. In this case, as when the solution is used, both the sulphur and potassium are oxidised. A description of this eudiometer, which has been but little used, is given in 'Nicholson's Journal,' 4to, vol. i.

The eudiometer of Seguin is a glass tube, about an inch in diameter, eight inches long, and open at one end. It is to be filled with and inverted in mercury; a small piece of phosphorus is then put under the open end of the tube, and by its lightness it immediately rises to the top of it, where it is to be melted by the approach of a red-hot iron. A measured portion of the gas to be examined is then to be passed into the tube; the phosphorus inflames on each addition of the gas, and the mercury rises, owing to the condensation of the oxygen. When all the gas under examination has been thrown up into the tube, the hot iron is again used to ensure the completion of the process. The quantity of the residual gas is determined by transferring it into a graduated tube, and the difference between the quantity submitted to experiment and that left after it, indicates the volume of the oxygen absorbed.

In this operation, owing to the affinity existing between the phosphorus and the oxygen, they combine and form phosphoric acid: it is however stated that the nitrogen absorbs a small quantity of phosphorous vapour, and that, owing to the expansion which this occasions, about $\frac{1}{10}$ of the volume of the nitrogen gas is to be deducted.

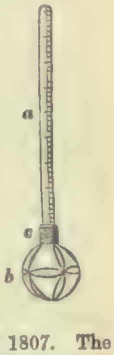
Berthollet also employed phosphorus in his eudiometer, but instead of heating it, as in the above-described method, he allowed combination to take place between it and the oxygen, by what is termed slow combustion. He exposed a stick of phosphorus fastened to a glass rod in a narrow graduated glass vessel, filled with air, and standing over water: the phosphorus immediately begins to act on the oxygen of the air, as shown by the formation of the white vapour of phosphorous acid; but this occurs without visible combustion. In six or eight hours the whole of the oxygen disappears, and its quantity is, of course, immediately apparent, making the deduction above stated from the nitrogen gas.

Dr. Hope's eudiometer is represented in the annexed figure. It is used with a solution either of sulphate of iron impregnated with nitric oxide or with solution of sulphuret of potassium. This eudiometer consists of a small bottle, capable of holding about three ounces, for containing the eudiometric fluid, and it is perforated and furnished with a stopper at *b*. Into the neck of the bottle a hollow graduated tube, *a*, closed at the upper end, is accurately fitted by grinding. It holds precisely a cubic inch, and is divided into 100 equal parts. To use the apparatus, the bottle is first to be filled with the solution to be employed, and, covering the mouth with a flat piece of glass, it is to be immersed in water; the glass being then removed, the open end of the tube containing the gas to be examined is to be inserted.



The instrument being removed from the water, is to be inverted. The gas ascending into the bottle, it is to be brought into thorough contact with the liquid by brisk agitation, by which absorption of gas occurs. To supply its place, the stopper at *b* is removed under water, a quantity of which rushes into the bottle; the stopper is then replaced, and these operations are alternately renewed till no further diminution takes place. The tube *a* is then withdrawn, the neck of the bottle being in water, and it is held inverted for a short time, and the diminution is then measured by the graduated scale.

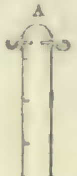
Dr. Henry has pointed out some difficulties attendant upon the use of this eudiometer, to obviate which he has substituted a caoutchouc bottle for the glass one, as shown in the annexed figure at *b*. The tube *a* is accurately ground into a short piece of very strong tube of wider bore, as shown at *c*, the outer surface of which is made rough by grinding, and shaped as represented, that it may more effectually retain the neck of the elastic bottle when fixed by waxed thread. This instrument is used in every respect in the same manner as Dr. Hope's. The only difficulty is in returning the whole of the residuary gas into the tube; but the art of doing this is readily acquired by practice.



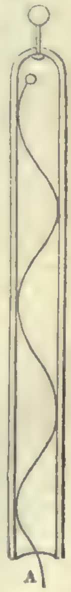
Pepys contrived a eudiometer in which a caoutchouc bottle was employed, as in Dr. Henry's. This instrument, from the inventor's statement, appears to be susceptible of great accuracy; for he states that he is able to measure an absorption of only $\frac{1}{1000}$ of the gas employed. For an account of this eudiometer, and of some experiments performed with it, see 'Phil. Trans.,' 1807. The parts are too numerous for us to insert figures of, and without them a description would be scarcely intelligible; besides, the apparatus is now superseded by others.

Having now described the use of nitric oxide, sulphuret of potassium, and phosphorus, as eudiometrical substances, and mentioned the more important instruments in which they are employed, we shall notice the eudiometer of Volta, and the eudiometric body which he made use of.

Volta's method of determining the composition of atmospheric air, or of the quantity of oxygen contained in gaseous mixtures, was by means of combustion with a known volume of hydrogen gas; for it having been ascertained that when a mixture of oxygen and hydrogen gases is fired, one-third of the diminution is owing to the condensation of oxygen, we have only to observe the measure of the contraction of volume to ascertain that of the oxygen which was present. Of Volta's eudiometer various modifications have been proposed, all agreeing however in the principle above mentioned. According to Berzelius, that invented by Mitscherlich is to be preferred, on account of the simplicity of its construction and the accuracy of its results. We shall, therefore, describe it instead of the original one, and it will at once occur to the chemical reader that it is a slight modification of Priestley's and Cavendish's detonating tubes.

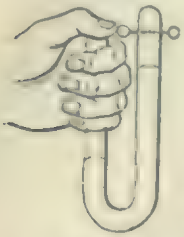


This instrument, as represented by the annexed figure, consists of a very thick glass tube, from 18 to 24 inches long, and about 4 lines internal diameter; it is graduated, open at one end, and closed at the other. Near the top (A) the tube is perforated with platinum wires, placed at such a distance as readily to allow of the passage of the electric spark between them, and externally hooked; near the orifice (B) the tube is laterally perforated and furnished with a glass cock, which is shut after filling the tube with the gas to be examined: this is, of course, to prevent the loss of gas by the expansion accompanying the detonation by the spark. When this is over, the cock is turned under either water or mercury, and the fluid rising in the tube, the condensation is exactly noted by bringing the fluid within and without the tube to the same level.



Another variety of Volta's eudiometer is represented by the opposite figure. It is more simple in its construction than the foregoing, but less certain in its results, on account of the escape of gas which occurs if it be not immersed sufficiently deep in water or mercury: it is a modification of an instrument invented by Dr. Priestley. The only additional explanation required is, that A is a moveable metallic wire with a knob at the end, which is raised near enough to the knob at the top of the instrument to allow of the passage of the electrical spark.

Dr. Ure also contrived a modification of Volta's eudiometer, which renders the experiment easy of performance by a single person. This instrument is shown by the figure. It consists of a glass siphon, having an interior diameter of from 2-10ths to 4-10ths of an inch; its legs are nearly of equal length, each being from six to nine inches long. The open extremity is slightly funnel-shaped; the other is hermetically sealed, and has two platinum wires inserted: the legs are about one-fourth to one-half an inch asunder. The instrument having been graduated, it is to be filled with water or mercury, and the gas transferred into it in the ordinary manner; then being upright, part of the fluid in the open leg is displaced by inserting a glass rod, or in some other manner. The open leg ought to contain at least two inches of air between the thumb and the mercury: this atmospheric column serves as a recoil-spring, enabling the operator to explode considerable quantities of gas without inconvenience or danger. The open leg being grasped by the hand, the thumb is to be placed lightly over the aperture, so as to close it, and at the same time to touch one of the wires; a spark taken from the conductor to the other wire passes through the gas, inflaming it, and is conducted off by the thumb and hand. The gas in expanding depresses the fluid beneath it, whilst, as already noticed, the air in the part inclosed by the thumb acts as a spring to restrain the violence of the explosion. If a charge from a jar is to be passed, then the thumb must not be allowed to touch the wire whilst closing the aperture. When the jar is charged, the wire connected with the outer coating is first to be hooked upon the eudiometer wire nearest the thumb, and securely retained there, so as not to slip during the experiment; and then the knob of the jar is to be brought to the other wire and the gas inflamed.



After explosion, when the condensation of volume ensues, the thumb will feel pressed down to the orifice by the superincumbent atmosphere. On gradually sliding the finger to one side and admitting the air, the mercurial column in the sealed leg will rise more or less above that in the other; mercury is then to be poured in till the equilibrium is restored, and the resulting volume of gas is then read off.

Dr. Ure states that with the above instrument he has exploded half a cubic inch of hydrogen mixed with a quarter of a cubic inch of oxygen, as also a bulk nearly equal of an olefiant gas explosive mixture, without any unpleasant concussion or noise.

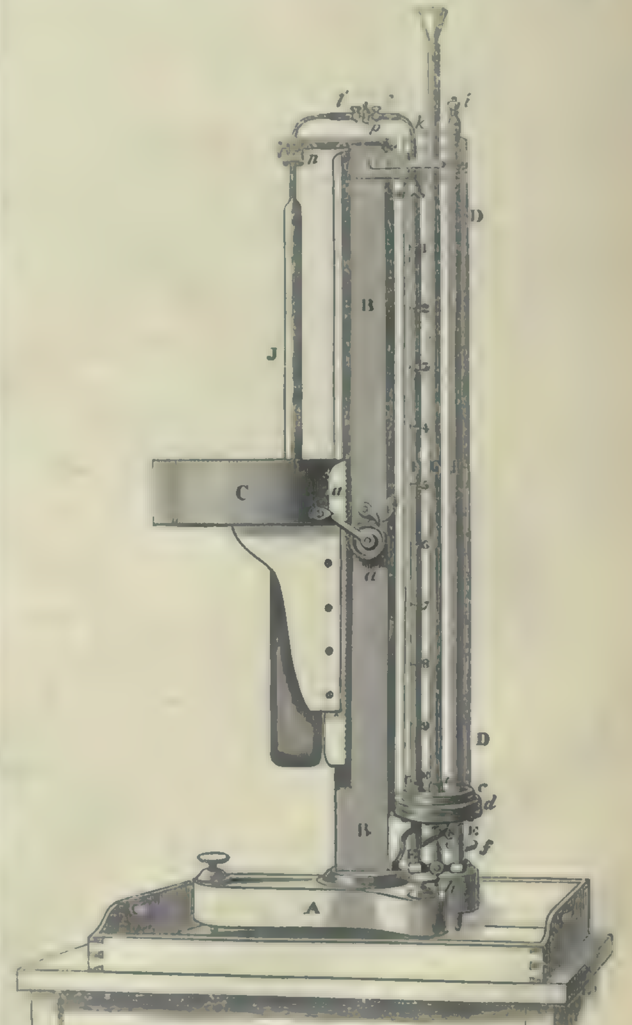
Döbereiner suggested a eudiometrical process, founded on his curious discovery of the property which spongy platinum possesses of causing the combination of oxygen and hydrogen gases. In this eudiometer the combination occurs without explosion, and yields results of considerable accuracy. Döbereiner found that when the spongy platinum was mixed with certain substances, so as to prevent its immediate and explosive action, it caused the oxygen and hydrogen to combine with moderate rapidity. The late Dr. Henry, who performed a most important and accurate series of experiments on this eudiometrical process, recommended a mixture of three parts of spongy platinum and two of fine china clay made into a paste with water and moulded into spherules about the size of a pea; these were fastened to a platinum wire, that they might be removed after the action was over. They should be heated and suffered to cool a short time before use: they suffer no loss of power, and possess the great advantage over the electric spark, that they act upon gaseous mixtures which contain so little oxygen and hydrogen that they cannot be fired. The late Dr. Turner ascertained that it was possible to determine the presence of $\frac{1}{100}$ of hydrogen or oxygen in a gaseous mixture; whereas, when these gases formed $\frac{1}{11}$ of a mixture, they could not be detected by electricity. The effect takes place more rapidly in large than in small tubes.

There are various gases which impede the action of the platinum balls. It appears from the experiments of Dr. Henry, that when the compound combustible gases, mixed with each other, with hydrogen, and with oxygen, are exposed to the balls of platinum, the several gases are not acted upon with equal facility: that next to hydrogen carbonic oxide is most disposed to unite with oxygen, then olefiant gas, and lastly, light carburetted hydrogen.

Dr. Henry observed, that the property inherent in certain gases of retarding the action of platinum, when they are added to explosive mixtures of oxygen and hydrogen, is most remarkable in those which possess the strongest attraction for oxygen. Heat occasions the platinum balls to act in many cases in which no combination would occur without it.

The instruments and methods above described were not only almost exclusively limited to the determination of the oxygen in atmospheric air, but they were also both imperfect and incorrect, and the analysis of gaseous bodies cannot be said to have become organised into anything like a system until Professor Bunsen applied himself to its improvement, which he effected less by the use of new instruments than by the perfection of the old ones, and the correction of the numerous sources of error which rendered the results of earlier experimenters so little trustworthy. To this accomplished chemist, to Regnault and others, this branch of chemical analysis owes its present state of perfection, which is rarely equalled and never surpassed in other departments of analytical chemistry.

Ingenious instruments for the analysis of gases have been contrived by Messrs. Regnault and Reiset (see 'Annales de Chimie et de physique,' t. xxvi., p. 333) and by Drs. Williamson and Russell ('Philosophical Magazine,' vol. xvi., p. 524) but in this article we shall confine ourselves to the description and use of an apparatus invented by Messrs. Frankland and Ward, which may be employed in all the operations of gaseous analysis, and which is represented in the annexed figure. A is a tripod base furnished with levelling screws and carrying the vertical pillar B B which supports on one side the moveable gutta percha mercury trough C, with rack and pinion *a a*, and on the other the glass cylinder D D with its contents. This cylinder is 36 inches long and 4 inches internal diameter; its lower extremity is cemented into an iron ring *c*, the under surface of which permits of being screwed watertight upon the iron platform *d* by the intervention of a caoutchouc ring. The circular platform *d* is pierced by three tubes which terminate below in the T piece E E. Into these tubes are screwed the steel caps *c c c* which receive the open extremities of the glass tubes F, G, H. The T piece E E is furnished with a three-way cock *f*, and with a simple cock *g*, by means of which the tubes in D D can be connected either with each other or with the exit nozzle *h*. Of the glass tubes F G H, one F is only slightly shorter than the containing cylinder, another H is 3 or 4 inches longer, whilst G rises at least 6 inches higher than the latter. F and H are each about 15 millimeters diameter; G is somewhat wider and open at top. H has a millimeter scale etched upon it, and its upper extremity terminates in a small funnel *i*, the throat of which can be closed by a ground stopper. The



tube F terminates in the capillary tube *k* which is cemented into the steel stopcock *l*; two platinum wires fused into this tube at *m* admit of an electric spark being passed through any gaseous mixture it may contain. This tube is graduated into ten divisions of equal capacity. A tube J, open below and terminating above in the stopcock *l'* is held in its place by the clamp *n*, and can be connected with the stopcock *l* by the junction piece *p*.

The instrument must now be levelled, and the height of each division upon F above the zero point of the millimeter scale on H must be determined by opening their upper extremities and filling them with successive quantities of mercury up to the different divisions upon F, noting at each division the height of the mercury in H. Before use, the cylinder D D must be filled with water, and the interior of the tubes F and H moistened with a few drops of distilled water introduced through the stopcock *l* and the funnel *i*. The three tubes being now placed in communication, mercury must be poured into G until it rises into *i*, when the stopper must be firmly inserted. As soon as the mercury flows from *l* that stopcock must also be closed. The tube J is then to be filled with mercury and attached by the clamp *n* and junction piece *p* to the stopcock *l*, and a glass tube about 2 feet long passing through the table upon which the apparatus stands, and terminating in a vessel below, being attached to the exit pipe *h*, the instrument is complete.

In order to illustrate the method of using this apparatus, let us suppose that an analysis of atmospheric air has to be made. Three or four cubic inches of atmospheric air, previously freed from carbonic acid, are thrown up into the tube J, and passed through the stopcocks *l l'* into the tube F, a transference which is accomplished by placing the three-way cock *f* in such a position as to connect F with the exit tube *g*, through which the mercury flows out as the gas enters above. This operation is facilitated by simultaneously raising the trough C. As soon as the transference is complete the cock *l* is shut, and *f* so placed that F and H are connected with *h*. Mercury is allowed to flow from *h* until a vacuum of 3 or 4 inches in length is produced in H and the highest point of the metal in F stands somewhat lower than one of the divisions upon that tube. The cock *f* must now be reversed, and *g* slightly opened so as to allow mercury to flow into F and H until its highest point in F exactly coincides with one of the divisions. The height of the quicksilver in H must now be exactly determined by reading through a horizontal telescope placed at a distance of about 6 feet. If from the number thus read off the height of the particular division at which the mercury stands in F be deducted, the remainder will represent the true volume of the gas; since the tension of aqueous vapour in F neutralises or corrects that in H, whilst the temperature of the tubes being maintained constant during the course of the analysis by the water in D D, no correction for variation of temperature requires to be made, and as the tubes in which the volumes are determined are completely shut off from all communication with the atmosphere, the barometrical changes which would otherwise affect the volume of the gases are entirely without influence upon this apparatus.

Hydrogen in the proportion of half the volume of the air used must now be passed into J, and thence into F, where the volume of the mixed gases must be again determined as before. An electric spark must now be passed through the mixture in F by means of the platinum wires at *m*. A slight explosion follows, and a considerable contraction in volume of the gaseous mixture also occurs; this contraction must be accurately measured by a new determination of the volume of the gases remaining in F. One-third of the contraction thus measured represents the volume of oxygen contained in the air submitted to analysis, and as the air employed consisted only of oxygen and nitrogen, it follows that the estimation of the former gas determines also the volume of the latter.

Having thus described the construction of this instrument, we will now proceed to notice the methods by which, with its aid, the different gases are separated from each, and the volume of each determined.

The volumes of the separate constituents of a gaseous mixture can be ascertained either 1st, by direct determination; or 2nd, by indirect determination.

1.—*Direct determinations.*

The chief gases which permit of being thus determined are the following:—

Carbonic Acid.
Oxygen.
Olefiant gas, or Ethylene.
Carbonic Oxide.

On the supposition that all these gases were present in a mixture to be analysed, the following operations would be necessary for the direct determination of each.

First, pass a convenient volume of the gas into the tube J, allow it to pass over into F until the mercury rises into the bend of the capillary tube *n l'*, and determine its pressure at any convenient mark on the latter tube; then pass up into J by means of a curved pipette, one or two drops of a concentrated solution of caustic potash, which will immediately ascend to the top of the tube. Now return the gas into J, and let a quantity of mercury trickle over after it. As the gas depresses the mercury in J, the caustic potash moistens the interior surface of that portion of the tube occupied by the gas, whilst the drops of mercury falling over from *k* greatly facilitate the action of the alkaline liquid by bringing every portion of the gas into contact with it. In three minutes the whole of the carbonic acid is absorbed, and the residue must now be transferred back into F for re-measurement of pressure at the same mark upon F, great care being taken that the caustic potash solution does not pass the point between *n* and *l'* to which the mercury was allowed to rise in the previous transference. The difference between this and the former measurement represents the volume of carbonic acid absorbed by the caustic potash.

From two to six drops of a strong solution of pyrogallic acid must now be thrown up into J, and the gas being again brought over from F, the oxygen which it contains will be completely absorbed in a few minutes, the liquid in J becoming of an intense blood-red colour. The re-measurement of the gas, with the same precautions as before, gives the volume of oxygen in the mixture.

The gas being retained in F, the tube J must be detached from the apparatus, thoroughly cleansed, by washing with water, and then dried, first with bibulous paper, and afterwards by a current of warm air, care being also taken to get the capillary tube perfectly dry. The tube whilst still warm must be completely filled with mercury by immersing it as deep as possible in the well of the trough C, and then applying suction to the orifice of the cock *l'*. Being now attached as before to *l*, the residual gas in F must be completely drawn over into it, but in such a manner as to avoid the ingress of mercury which might carry over with it some moisture from the tube F. The absorption of olefiant gas must now be effected by introducing into J a coke bullet saturated with a solution of anhydrous sulphuric acid in nordhausen sulphuric acid. The coke bullet is made by placing the bent end of a piece of thin platinum wire in a bullet-mould about half an inch in diameter, then ramming the mould full of a finely powdered mixture of two parts of coke and one of bituminous coal, and finally heating both the mould and its contents to redness for fifteen minutes. The bullet must be removed from the mould so soon as the latter has cooled, and excrescences being removed by a knife, it must be immediately plunged into the acid mixture just indicated. The piece of platinum wire serves to introduce it into J, an operation which must be performed with only momentary exposure of the fuming ball to the air, so as to avoid the access of atmospheric moisture, which would combine with the anhydrous acid and render it incapable of absorbing olefiant gas. The absorption of the olefiant gas takes considerably more time than that of the two first gases, and the ball must not be removed from the tube until an hour at least has elapsed. The residual gas is now contaminated with sulphurous acid and the vapour of anhydrous sulphuric acid, from both of which it is however at once freed by passing up into J two or three drops of concentrated potash solution. The residual gas being again measured in F as before the diminished pressure represents the volume of olefiant gas which has disappeared.

The remaining gas in the above list—carbonic oxide—is usually determined by the indirect method mentioned below, there are however certain cases in which its direct determination is desirable, although it is always less accurate than the indirect one. The direct determination of carbonic oxide is effected by absorption with solution of dichloride of copper; the latter is best prepared by allowing a concentrated solution of proto-chloride of copper to stand in contact with copper turnings in a closely-stopped bottle for several days. A quantity of this solution, equal in volume to about one-fourth of the carbonic oxide to be absorbed, must be passed up into J, and the gas being brought over from F must be left for five or ten minutes in contact with the solution, whilst a stream of mercury falls through it as in the two first determinations. The pressure of the gas being again measured, gives the volume of carbonic oxide absorbed.

The determination of any one of these gases in the absence of the others is effected in the same way, viz:

Carbonic acid by absorption with caustic potash;

Oxygen by a mixture of caustic potash in excess with pyrogallic acid;

Olefiant gas by anhydrous sulphuric acid; and

Carbonic oxide by dichloride of copper.

2.—*Indirect determinations.*

The following are the most important gases which are usually determined by the indirect method:—

Hydrogen.
Light carburetted hydrogen.
Carbonic Oxide.
Nitrogen.

The estimation of these gases even when all four are present in a mixture, is at once simple, expeditious, and accurate. It consists in exploding a known volume of the mixture in the tube F of the apparatus with an excess of oxygen, and then determining, 1st, the diminution of volume of the gaseous mixture after explosion; and 2nd, the volume of carbonic acid produced by the combustion. The residual gas remaining after absorption of carbonic acid consists of nitrogen mixed with the excess of oxygen previously added; the volume of the former is of course determined if we estimate that of the latter, which is effected by adding to the mixture of the two gases from two and a half to three times its volume of hydrogen, exploding in F and measuring the contraction produced exactly in the manner already described above for the analysis of atmospheric air.

The operations just described give us the following four data from which it is easy to determine the respective volumes of two or more of the four gases present in the mixture :—

1. The volume of the gas taken for analysis . . = A
2. The volume of the combustible gases present . . = A′
3. The contraction of volume on explosion . . . = C
4. The volume of carbonic acid generated on explosion = D

It will be seen that the value of A′ is ascertained by deducting from A the volume of nitrogen in the mixture, determined as just described.

The respective volumes of the three combustible gases are determined from the consideration of the contraction, and the volume of carbonic acid, produced by each on explosion, with excess of oxygen, as seen in the following table :—

Name of Gas.	Volume of Gas.	Contraction of volume on explosion with excess of oxygen.	Volume of carbonic acid produced by explosion with excess of oxygen.
Hydrogen . . .	1	1·5	0
Carbonic oxide . . .	1	0·5	1
Light carburetted hydrogen	1	2·0	1

If we now represent the volumes of nitrogen, hydrogen, carbonic oxide, and light carburetted hydrogen respectively by the letters w, x, y, and z, we have, taking the data just given, the following equations, expressing the volumes of the four gases present in the mixture submitted to analysis :—

$$w = \mathrm{A} - \mathrm{A}'$$

$$x = \mathrm{A}' - \mathrm{D}$$

$$y = \frac{3\mathrm{A}' - 2\mathrm{C} + \mathrm{D}}{3}$$

$$z = \frac{2\mathrm{D} - 3\mathrm{A}' + 2\mathrm{C}}{3}$$

If, on the application of these formulæ to the results of an analysis, the value of any letter be either a small negative quantity or = 0, it follows that the gas denoted by the letter is not present in the mixture.

The only difficulty likely to arise in making such indirect determinations, consists in adding neither too much nor too little oxygen to the combustible gas, since, when too much is added, either no explosion ensues on passing the electric spark, or, if the ignition of the mixture be effected, and light carburetted hydrogen or carbonic oxide be present, the temperature is too low to ensure the complete oxidation of these gases; whilst when too small an excess of oxygen is added, the violence of the explosion is so great as to endanger the rupture of the glass tube containing the gases. It is not difficult to avoid these contingencies where the nature of the gaseous mixture experimented upon is approximately known, if it be borne in mind that, of the three combustible gases above mentioned, each volume of hydrogen or carbonic oxide requires about 1¼ volumes, and each volume of light carburetted hydrogen about 5 volumes, of oxygen, for successful combustion.

We have thus given a very condensed account of this branch of chemical analysis; but for more minute details the reader is referred to the article 'Analyse fur Gase' (by the writer of the present article), in the 'Handwörterbuch der Chemie,' by Liebig, Poggendorf and Wöhler, 2te, Auflage. In conclusion, and as an illustration of the application of these analytical processes, we shall now describe the mode of performing an analysis of coal gas.

Analysis of Coal Gas.—Purified coal gas generally contains the whole of the following ingredients :—

1. Olefiant gas and analogous hydrocarbons.
2. Light carburetted hydrogen.
3. Hydrogen.
4. Carbonic oxide.
5. Carbonic acid.
6. Oxygen.
7. Nitrogen.

Of these ingredients, the first, fifth, and sixth are determined by the direct, and the rest by the indirect, methods above described.

Two or three cubic inches of the gas are passed into the tube J, and subsequently into F, for measurement. The oxygen, carbonic acid, and olefiant gas are now successively estimated in accordance with the methods described under the head of *Direct Determinations :* the mode of absorbing olefiant gas there given also effects the simultaneous removal of the analogous hydrocarbons, to which, in part, the diminution in volume will therefore be due. The remaining gas must now be exploded with about three times its volume of oxygen, and the respective volumes of the four remaining gases determined as described under *Indirect Determinations.*

This estimation of the relative quantities of the several constituents of coal gas does not give any absolute data from which the illuminating power and consequently the commercial value of coal gas can be calculated. It gives us, it is true, the amount of illuminating hydrocarbons (olefiant gas and analogous hydrocarbons) to which exclusively the illuminating power of coal gas is due; but as these vary in their light-giving powers in direct proportion to their richness in carbon, it follows that their value can only be estimated by determining the amount of carbon which a given volume of them contains. This can easily be effected by the additional operation of ascertaining the amount of carbonic acid generated by a given volume of the coal gas on explosion with oxygen, and comparing this with the amount produced on the explosion of the residual gas remaining after the abstraction of the hydrocarbons. For this purpose a known volume of the original gas is introduced into F (see *fig.* col. 320), and mixed with five times its bulk of oxygen; the electric spark is passed, and the volume of carbonic acid generated by the explosion ascertained by absorption with caustic potash in J. If we now denote the per-centage of hydrocarbons absorbed by anhydrous sulphuric acid by A, the volume of carbonic acid generated by 100 volumes of the original gas by B, the carbonic acid formed by the combustion of the non-luminous constituents remaining after the absorption of hydrocarbons from the above quantity of original gas by C, and the volume of carbonic acid generated by the combustion of the luminiferous hydrocarbons by x, we have the following equation :—

$$x = \mathrm{B} - \mathrm{C}$$

Consequently, the amount of carbonic acid generated by one volume of the hydrocarbons will be represented by

$$\frac{\mathrm{B} - \mathrm{C}}{\mathrm{A}}$$

Now, as the amount of carbon in each volume of the illuminating hydrocarbons is directly proportional to the volume of carbonic acid which these hydrocarbons produce on combustion, it follows that the formula just given expresses the illuminating power of the gas. For comparison, it is convenient to take as a standard the illuminating or carbon value of olefiant gas, which generates twice its own volume of carbonic acid. In order, therefore, to express the value of the luminiferous hydrocarbons of any sample of gas, in units of olefiant gas, it is only necessary to change the last expression into

$$\frac{\mathrm{B} - \mathrm{C}}{2\mathrm{A}}$$

Thus, any sample of gas containing 10 per cent. of hydrocarbons, of which one volume generates three volumes of carbonic acid, will have an illuminating effect equal to another gas containing 15 per cent. of olefiant gas. This method, therefore, furnishes us with an exact chemical standard of comparison for the illuminating value of every description of coal or other gas in use as a source of artificial light.

GAUGING is the method of determining by actual measurement the number of gallons contained in any vessel intended to hold goods. The greatest use of this art is in the collection of the revenue, in which it is necessary to measure the bulk of vessels without disturbing their contents. For this purpose a number of rules have been laid down by various writers, of whom the reader who is interested in the subject may consult Leadbetter's 'Treatise on Gauging,' John Ward's 'Young Mathematician's Guide,' or Dr. Hutton's 'Mensuration.' The rules laid down were, in many cases, of uncertain application; as, for instance, a close cask was to be treated either as a frustum of a spheroid, or of a parabolic spindle, or as a double frustum of a paraboloid, or else of a double cone, according to its appearance. The allowance made for the thickness of a cask was a guess, and the method of using *small* sliding-rules, to which supervisors formerly resorted to escape calculation, is a species of estimation which would never have been tolerated in money transactions between man and man. The inference to be drawn from the art as described by early writers, is that, generally speaking, the results of excisemen's measurements were below the truth: had it been otherwise, the fact could not but have been known to merchants and tradesmen, who can gauge their own vessels after the contents are removed, or who learn their bulk in the removal. If the methods of the excisemen were tolerably uniform, which is perhaps pretty nearly true, if we may judge from writers on the subject, no injustice was done by unequal taxation, and the government would probably have found it as easy to increase the duties, as to raise an additional revenue from a more correct method of collecting the old one.

With *larger* sliding-rules for calculation, and the aid of habit derived from experience, it is possible very accurately and easily to measure casks which do not depart much from a given standard of form. This is what is done by gaugers at the present time; and their practice has attained considerable accuracy. In a particular instance which has come to our knowledge, and in the case of a vat which held 6500 gallons, the measurement of the exciseman did not differ more than ten gallons from the truth. This degree of accuracy is entirely modern, and must in a considerable degree arise from similarity of form being very nearly preserved in the different species of casks.

The great variety of cases which occur would make a summary inconveniently long. Wherever a content is to be found, either the figure itself is simple and regular, as in the case of a cylinder, or nearly a simple figure, as in the case of some casks, which may be considered as the frusta of spheroids [see BARREL as an instance of the approximating supposition], or so irregular that the content can only be found by dividing them into a considerable number of sections, and considering each section as a small cylinder or frustum of a cone. [QUADRATURES, METHOD OF.]

The work on gauging which is most commonly used, is Symon's 'Practical Gauger,' which has been through several editions. Other works are, those of Leadbetter, Shirtcliffe, Moss, Gutteridge, and Iley. The first three are of the first half of the last century, and that of Shirtcliffe contains theoretical investigations. Ward's 'Mathematician's Guide,' and Hutton's and Bonnycastle's 'Mensuration,' contain small treatises on the subject.

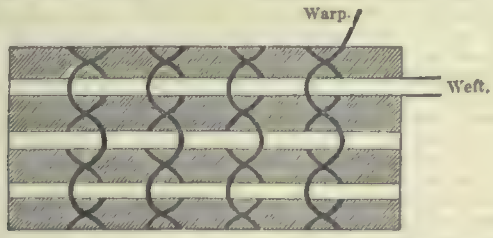
GAULS. [CELTÆ.]

GAULTHERIC ACID. [ESSENTIAL OILS. *Essential oil of Wintergreen.*]

GAULTHERILINE. [ESSENTIAL OILS. *Essential oil of Wintergreen.*]

GAUZE, a light transparent texture, made of fine silken threads. Its name has led to the conjecture that this fabric was first invented in Gaza, a city of Palestine. Spitalfields was, some years back, the principal seat of the silk-gauze manufacture in Great Britain; but of late Paisley and Glasgow, and the villages near those towns, have almost entirely engrossed this branch of husbandry; although some is made in the Derbyshire and Lancashire districts.

Gauze is one of the very few silken fabrics in the making of which the British manufacturer is still excelled by the French, both as to cheapness and quality. This cheapness results from the lower rate of wages paid to the French weavers as compared with ours; since the weight of silk contained in a yard of gauze is so trifling as to make the value of the material bear but a small proportion to that of the labour employed in its conversion.



The texture of gauze is different from that of plain weaving, in which the warp, or longitudinal threads, are always parallel to each other. The essential character of gauze-weaving is that between each cast of the shuttle a crossing of the warp threads shall ensue, and thus the weft (which forms the cross-threads interlaced by the warp) is not brought into absolute contact with the cross-thread immediately preceding. The intervals left between the interlacings cause that degree of transparency which, without such arrangement, could only result from a looseness of texture incompatible with beauty and utility.

In the present days of cheapness and imitation, gauzes, or textile fabrics receiving that name, are sometimes made of a mixture of silk and cotton; or even of cotton alone.

GAVELKIND, a customary tenure existing at this day in the county of Kent only. It seems that this tenure was the common socage tenure among the Anglo-Saxons (Glanvil, l. 7, c. 3), and the reason of its continuance in Kent has been ascribed to the resistance which the inhabitants of the county made to the Norman invaders. This tenure also prevailed in Wales until the 34th Henry VIII., when it was abolished by statute. The various derivations of the term Gavelkind which have been suggested are given in the 1st chapter of Robinson's 'Treatise on Gavelkind.' The distinguishing properties of this tenure are: "That upon the death of the owner without a will the land descends to all the sons in equal shares, and the issue of a deceased son, whether male or female, inherit his part; in default of sons, the land descends in equal shares to the daughters; in default of lineal heirs, the land goes to the brothers of the last holder; and in default of brothers, to their respective issue."

The tenant may alien at fifteen years of age, by means of a feoffment [FEOFFMENT], and the estate does not escheat in case of an attainder and execution, the maxim being, 'the father to the bough, the son to the plough.' The husband is tenant by curtesy of a moiety of his wife's lands, without having any issue by her; but if he marries again, not having issue, he forfeits his curtesy. A wife is endowed of a moiety of the lands of which her husband died seised, not for life as by the common law, but during chaste widowhood only. Gavelkind lands also were generally devisable by will before the statute of wills was passed.

Several statutes have been passed, at the request of holders of gavelkind lands, to render them descendible according to the course of the common law, or, as it is called, to disgavel them. These statutes, however, only alter the partible quality of the customary descent; they do not affect the other incidents to the tenure. And notwithstanding the extent of the disgavelling statutes, it is always presumed that lands in Kent are of this tenure, until the contrary is proved.

This tenure existed also in Ireland as an incident to the custom of tanistry—and as such ceased with that custom in consequence of the judgment against it. (Davis's 'Reports,' 28.) In the reign of Queen Anne, with the view of weakening the Roman Catholic interest in Ireland, the land of Roman Catholics was made descendible according to the custom of gavelkind, unless the heir conformed within a limited time; but by the stat. 17 & 18 Geo. III. c. 49 (Irish), the lands of Catholics are made descendible according to the course of the common law. (Robinson, p. 21.)

This customary descent is followed in some manors, particularly in the manors of Stepney and Hackney. (See the custumal of those manors printed in 2 Watkins, 'Copyh.,' 508.)

GAVOT (*Gavotta*, Ital., *Gavotte*, Fr.), a lively dance of two strains, in duple time. This generally followed the minuet, and still succeeds the *Menuet de la Cour*, when the latter is introduced on the stage.

GAZETTE (*gazzetta* in Itallan, *gaceta* in Spanish) is the name given to newspapers in several parts of the Continent. The name was, according to Ménage and others, derived from a small Italian coin, which was the price of the first newspaper established in that country. In England the 'London Gazette' is an official advertiser, printed under the authority of government, as are also the Gazettes of Edinburgh and Dublin for Scotland and Ireland. They contain all proclamations, orders in council, promotions and appointments to commissions in the army or navy, the nomination of sheriffs, the appointment of ambassadors, consuls, and other civil officers of the higher ranks, and all matters done by the queen in her political capacity; the production of the Gazette being sufficient evidence in courts of law for transactions in consequence thereof, except in some special cases, as to commissions, in which the Gazette is only secondary evidence when the production of the commission itself is refused. They contain also notices of all bankruptcies, insolvencies, and sequestrations, with other matters connected with proceedings under them; and the insertion of such notices is made a legal notice by special enactment; but in cases of dissolutions of partnership, special notice should also be given to parties with whom the firm has had dealings. Notices are required to be given in the Gazette during October and November (before the meeting of parliament), of intended applications for what are called Private Acts, relating to inclosures, canals, railways, and such matters. By special enactment also, it publishes the weekly and monthly returns of the Bank of England, and the bank-note circulation of all the banks in the United Kingdom, the prices of corn, &c.

Gazetteer has been used in England to mean a geographical dictionary, such as Brookes' 'General Gazetteer,' and other similar works.

GEARING. The parts of machinery by means of which the motion communicated to one principal portion of an engine is communicated to the rest, are known by the generic name of gearing, and they may be either multiplying, or retarding, fixed, or moveable, straight or bevilled gearing.

Multiplying or retarding gearing is that which is used for the purpose of augmenting, or diminishing, the velocity of the first motion, and its action in this respect depends upon the relative dimensions of the wheels gearing into one another. As the word *gearing* is no doubt derived from the German root *gerathen* "to fall, or come in, or into," it should, strictly speaking, be only applied to teethed wheels, but by extension it is frequently made to include also both band and friction wheels, and indeed in some cases their action is so nearly the same as that of teethed wheels, that it is hard to draw the distinction between them. The principles upon which the proportions of the diameters, and the number of teeth in multiplying or retarding gear, are fixed, in simple terms may be stated as follows. The velocities of wheels gearing into one another are in the direct ratio of their diameters; and they are also in the direct ratio of the number of the teeth. For instance, a wheel three feet diameter gearing into a wheel of only six inches in diameter, will travel with a velocity which will be only $\frac{1}{6}$ of that of the latter; and a wheel with 72 teeth will revolve in twice the time of the revolution of a wheel with 36 teeth. When eccentric, or occasional movements are required to be transmitted, it becomes necessary to employ either cams or eccentric gearing. [MACHINERY, COMPOSITION OF.]

Gearing is said to be *fixed*, when it is not susceptible of being disconnected with, or detached from, its corresponding work; as for instance when wheels are keyed upon their axles, and permanently placed upon the leading or following wheels to which they serve as intermediaries. *Moveable gearing* may be either loose upon a fixed axle, as in the case of the different parts of a mill wherein two shafts revolve above, or by the side of, one another, and are put in relative motion by means of a pinion gearing into fixed wheels on the two shafts, but able to be itself detached from them, either by being moved horizontally, or vertically by means of a lever; or it may be fixed upon its axle when the latter is susceptible of being put out of gearing by a lateral motion, as in the case of the various motion shafts of a crab. The clutch boxes, by means of which the respective portions of a long shafting are placed in connection with one another, come under the definition of moveable gearing; and like all other gearing of the same description, they may be so combined as to allow the direction of the motion to be changed at will.

Straight, or spur gearing is that which is employed when the axes of the respective wheels and axles are parallel to one another; *bevilled* *gearing* is that which is used when it is necessary to change the direction of the original motion, either angularly on the same plane, or at a different elevation, in a perpendicular or angular direction. Sometimes bevilled gearing is formed by cutting the teeth of the wheels upon portions of cones working into one another; or by means of teeth cut upon the path of a screw, working into a worm cut upon the upright shaft.

Perhaps it ought to be added, that the periods of revolution of the different kinds of gearing, whether fixed or moveable, straight or bevilled, are quite as often equal, or synchronous, as they are slower or faster. When the periods of revolution are synchronous, the wheels are, of course, of equal diameters.

GEIC ACID. [GEIN.]

GEIN, a name given to *humus* in common with *ulmin*, *humic acid*, *ulmic acid*, *humin*, and *geic acid*. This substance is obtained from common mould, which when boiled with alkalies, and the solution filtered and treated with acids, yields a brown deposit, which has the above names. Mülder states that the substance contains 2½ to 7 per cent. of nitrogen. These substances appear to be vegetable matters in a state of decay.

The name *gein* has also been given to a bitter non-azotised matter found in the root of the *Geum urbanum*. Its composition is not known.

GELATIN. The physiological relations of gelatin, and its value as an article of food, have already been described. [GELATIN, in NAT. HIST. DIV.] The present article will, therefore, merely contain a description of its manufacture for commerce, and the chemical action of various substances upon it.

Parings of the hoofs and horns, the crushed bones, and the cuttings of the hides of animals, are placed in cast-iron cylinders, and subjected to the action of steam at ordinary or at a more or less increased pressure; a strong solution of gelatin in hot water is thus produced, which is poured out on to polished slabs of tin, marble, &c., to solidify, and the resulting sheets afterwards cut into shreds by machinery. If the gelatin is required for dietetic purposes, great care is observed in the selection and cleaning of the materials from which it is to be obtained. Some makers bleach it with sulphurous acid, flavour it with various essences, well dry and powder it to render it more rapidly soluble in water, and one patentee even takes the trouble to dry it in vacuo. Gelatin of a common description is used in pharmacy for making *capsules*, little bags intended to contain active medicinal preparations of nauseous taste and odour; also for coating pills. Sheet gelatin, coloured, is now largely used as an ornamental envelope for confectionary, &c., and in the fabrication of toys and other small articles.

Gelatin softens and swells up in cold water, but does not dissolve. It is also insoluble in alcohol, ether, and the fixed and essential oils. Boiling water dissolves it in considerable quantity. If a sheet of tolerably soft gelatin be printed upon, and then immersed in spirit of wine, a considerable but equal contraction takes place; and the print transferred to stone furnishes impressions similar to the original, but much reduced in size. By printing upon a sheet of very dry gelatin, and afterwards immersing in water, the converse of the above result is obtained.

Chlorine acts upon gelatin, forming with it a white compound, from which the gelatin may be reproduced unchanged on the addition of ammonia. Nitric acid converts gelatin into oxalic acid, and other products. Sulphuric acid transforms it into leucin, a kind of sugar called glycocin, and into some other products. Acetic acid dissolves gelatin; strong alkalies decompose it. Its aqueous solution is precipitated by bichloride of platinum, corrosive sublimate, infusion of galls, or any liquid containing tannin, but is not rendered even turbid by solution of ferrocyanide of potassium, a test by which gelatin is at once distinguished from albumen.

From the difficulty of obtaining gelatin in an absolutely definite condition, its true chemical composition is somewhat uncertain. The formula usually adopted for it is $C_{13}H_{10}N_2O_5$; this nearly agrees with the following per centage results obtained by Mülder :—

Carbon	50·40
Hydrogen	6·64
Nitrogen	18·34
Oxygen (including trace of sulphur)	24·62
	100·00

GELATINE AND GLUE. These nearly-allied substances may conveniently be noticed together, in relation to their manufacture and uses.

Gelatine.—Gelatine is used partly as an agent in food, and partly as a cement. Much of it exists in the bones of animals; and it affords one evidence of the improved processes of modern times, that so valuable a substance is now saved which used formerly to be wasted. The jelly can be obtained by the action of heat on the organised tissue of bones, tendons, ligaments, sinews, skin, and serous membrane, whilst in contact with water. Isinglass is nothing more than a purer kind of gelatine. All gelatines dissolve more or less in hot water, and form a translucent jelly. Gelatine and tannin form leather, a fact which explains the rationale of the tanning process.

Without touching in this article on the chemistry of gelatine as an article of food, we may mention that gelatine is nourishing as a diet, but not alone; for it is wanting in flesh-making elements. The late Sir Samuel Bentham, a person of great ingenuity, drew the attention of the Admiralty, in 1829, to the advantage and economy of supplying the navy with gelatine procured from bones, by a process invented by D'Arcet long before, and much practised in France. French workmen, and some of the inmates of French hospitals, are frequently supplied with soup made from bone-gelatine at a cost of one farthing per pint; and it could be made sufficiently strong to be portable when cold for one halfpenny. Bentham proposed that the bones of salt beef should not be thrown away, as at present, on shipboard. If the joints were deprived of the bone before the meat is shipped, the good beef could be packed in a small space, and thereby economise stowage on board; while the bones would be available as a source of gelatine. Beef bones contain 30 per cent. of gelatine, and 10 per cent. of fat, which can be extracted by processes easily managed. The gelatine could be flavoured and dried, and would be very valuable as an article of ship diet. The meat also could be more easily and perfectly salted, and could be rolled up like Hamburg beef before being put into the casks. Bentham, calculating on the basis furnished by the French chemists, asserted that the bones which are stripped of their meat every day in London, would furnish gelatine sufficient for one small basin of soup to every one of the inhabitants, young and old. He impressed his views on the Admiralty, but without success; and we believe bone-gelatine does not yet form an element in the dietary of the British navy. The French adopt the system much more extensively than ourselves. On the large scale, the gelatine is extracted by steam, and sometimes a little muriatic acid is employed to remove the phosphate of lime. Even *fossil* bones have been made to yield gelatine.

The power of obtaining gelatine from bones being once understood, the variety of applications becomes very considerable. Bone-gelatine, for divers purposes, is bleached with sulphuric acid or animal charcoal. It may be tinted blue by sulphate of indigo or juice of blue-berries; green, by the juice of spinach; or red by that of beetroot. Cake gelatine is made by the French from the cuttings of the skins used in kid-glove making. Nelson's patent gelatine is obtained from glue-pieces or cuttings from the hides and skins of animals. In preparing it, the fragments are freed from hair, wool, flesh, and fat; then steeped for several hours in a solution of caustic soda; then placed in covered vessels at a temperature of 60° or 70° Fahr.; next washed to expel the alkali; then exposed to the vapours of burning sulphur; and then dissolved in water at a temperature of 150° Fahr. After this, the solution is strained into settling vessels, where it is kept for several hours at a temperature of 110° Fahr. It is then poured to the depth of half an inch upon a cooling slab, and the resultant cake of jelly, after a few further processes, is prepared into one of two kinds, opaque or transparent—both intended as substitutes for isinglass. Rattray's patent gelatine is another kind, produced in a somewhat similar way from waste glove-pieces. Swinburne's patent gelatine is made from the cuttings of calves' skins. What is called *rough* gelatine is made from the spongy insides of the horns and ribs of oxen, and the softer parts of the skulls and other bones, also from sheep's bones—the preparation requiring, of course, a good deal of cleaning, steeping, boiling, steaming, evaporating, &c.

Glue. This thicker kind of gelatine is prepared from the clippings of hides, hoofs, &c., obtained at the tan-yard. The first operation is to wash this refuse in lime-water, and afterwards to boil it in water, and skim the solution, which is then rendered clear by being strained through baskets, and evaporated by a gentle heat to a proper degree of thickness. It is finally cooled in wooden vessels, cut into thin portions, and dried upon coarse net-work. When properly prepared, glue is of a deep brown colour, translucent, and free from spots and clouds. When required for use, it is broken into pieces, and steeped for about twenty-four hours in cold water, by which it swells and softens. When gently heated in a water-bath, such as the common glue-pot is, it is applied by means of a brush to the various kinds of work for which it is used. The adhesion depends upon the evaporation of the water. Mr. Tucker patented a process, in 1856, for drying glue without the use of a netting. He pours the boiled mass into separate pans disposed on racks in a drying chamber; heat is applied at a temperature of 140° or 150° Fahr., and fans are then rotated to send a current of air through the chamber. Another proposal for drying is to pass the glue into a vessel fitted with a horizontal metal cylinder, kept heated by steam within or by a steam jacket on the outside; the lower half of the cylinder dips into the glue, and revolves at a slow rate, the surface takes up a thin film of the glue, which quickly solidifies and dries; a film is thus formed and dried at each revolution of the cylinders.

Besides the application of gelatine to food, and that of glue as a cement, both are used in very numerous ways in the mechanical arts. Glue and treacle make a peculiar elastic substance very useful for printers' inking-rollers. Gelatine casts, and gelatine moulds for casts, are now very common—especially the latter, on account of the ease with which the casts can be taken out of them. The *gelatineurs* of Paris make sheets of exquisitely fine gelatine, dyed to the most brilliant colours. These sheets can be applied to many useful purposes; they can be used as a layer on the surface of an engraving or woven material to which it will serve as a varnish; they can be made into a substitute for carton, for address and visiting cards; they can be employed by wood engravers in transferring or copying designs; and when made extremely thin, they can be used as wrappers and envelopes for fancy articles, as materials for transparent artificial flowers, and as a substitute for paper on which printing in gold may be effected.

The *size* used by paper hangers, white-washers, &c. is a kind of thin glue made from parchment cuttings. Jeffery's *marine glue*, an uncommonly powerful cement used in shipbuilding, is not properly a glue at all; it is a combination of other substances than gelatine.

GE'MINI (the twins), the third constellation in the Zodiac. The Greeks refer it not only to the fable of Castor and Pollux, but also to those of Hercules and Apollo, Triptolemus and Iasion, Amphion and Zethus, &c.

The principal stars are as follows:—

Character.	No. in Catalogue of Flamsteed.	No. in Catalogue of British Association.	Magnitude.
μ	13	2047	3
γ	24	2163	2·5
ε	27	2194	3
θ	34	2237	4
α	66	2485	1

This constellation derives its name from two remarkable stars, of the first and second magnitude, to which the names of Castor (or α Geminorum) and Pollux (or β Geminorum) are given. The latter star is marked by Flamsteed as of the first magnitude, by the greater part of astronomers as of the second, and by Piazzi as of the third! These two stars, whose proximity will cause them to be easily recognised when once known, may be found by drawing a line through the belt of Orion and the two bright stars the line of which cuts through the belt. This line, lengthened upwards, will pass very near to the two stars of Gemini. They are also about halfway between Regulus and Aldebaran: and if the Great Bear and Orion be seen together, then Capella on the one side, and Castor and Pollux on the other, will be conspicuous boundaries of the intermediate space.

GEMS. [CAMEO; INTAGLIO.]

GEMS, ARTIFICIAL. [GLASS.]

GENDARMERIE (from *Gens d'Armes*, men-at-arms) was a chosen corps of cavalry under the old monarchy of France: it is mentioned with praise in the wars of Louis XIII. and Louis XIV. Under the present system the gendarmerie is a body of soldiers entrusted with the police all over France; it furnishes patrols, arrests criminals, examines the passports of travellers, and contributes to the maintenance of good order. Gendarmes are generally stationed at the barriers or gates of the towns, at the principal inns on the roads, at markets and fairs, and along the lines of the frontiers. They are divided into foot and horse: *gendarmes à pied*, *gendarmes à cheval*. They form a distinct corps in the army, under their own superior officers, who are under the orders of the ministers of the interior and of police; but in case of war, they may be called into active service like the other corps of the army. The gendarmerie is mostly recruited from old and deserving soldiers of other regiments, who consider it as a promotion, as they have better pay and enjoy greater liberty. This explains why the gendarmes, generally speaking, are remarkably well behaved and trusty men, who, while strictly executing their duties, behave with considerable civility towards unoffending people, such as travellers, and especially foreigners. The same description of troops exists in the Italian states, where they are called Carabineers.

GENDER is a grammatical principle entering into the structure of many languages, according to which nouns are distributed into classes. There are, strictly speaking, but two genders, *masculine* and *feminine*; those which belong to neither of those classes were said to be *neutrius generis*, of neither gender: this third class are called somewhat incorrectly *neuters*, and hence by a second irregularity it is the ordinary practice of grammarians to speak of three genders.

That sexual distinction was the fountain from whence the doctrine of grammatical gender was derived cannot be reasonably disputed. As a consequence of this the principle must have been confined originally to living beings, and among these it must have been still further limited to those animals where the distinction of the sex was readily perceived, as in the mane of the lion, the plumage of the peacock, or the magnitude of the bull. In the smaller animals it would be often difficult to ascertain the sex, and useless to denote it. But utility and truth are not the sole governing principles of language; they are often sacrificed to the love of imagery and personification. Thus the beautiful and pleasing absurdity which characterises the language of fable recommends itself to the infant mind whether of the savage or the child. The rose, the lily, the sun, the moon, are all endowed with the faculty of speech, and it then becomes almost necessary to add the distinction of sex. Here the choice must depend upon the association of ideas. Action, freedom, strength, magnitude, and violence, are the marked attributes of the male; sufferance, subjection, timidity, together with pregnancy, of the female. In the application of these notions, the realities of nature are often neglected. The domestic animals, having lost all the violence of the natural state, convey to the mind the idea of something feminine. Thus among the Romans even the dog was in ordinary language considered to be of that gender, perhaps because it was inferior in power to the wild wolf; while the English, contrasting that noble and powerful animal with the clean and delicate but irritable cat, have allotted the masculine gender to the dog, to the other the feminine. The feathered creation again, by their small size, their weakness, and the delicacy of their plumage, are naturally associated with the tender sex, with the exception commonly of the eagle, kite, hawk, &c.

In the meanwhile the neuter is employed to denote that the notion of gender is not entertained; it is therefore, as Grimm has well observed, the proper grammatical form for the young of animals, where the sexual distinctions are imperfectly developed. Thus in the greater part of the Teutonic languages, the terms for *foal*, *calf*, *lamb*, *child*, &c., are of the neuter gender; and in the Greek there occur many similar forms, as τεκνον, βρεφος, &c. Hence, by an easy connection the diminutives generally in the Greek and Teutonic languages are of the same gender; and this principle is carried to such an extent that a neuter diminutival suffix is at times employed in the formation of the names of women, as *Dorcium*, *Glycerium*, in Terence, *mägdchen*, *Gretchen*, "little Margaret" in German. In the further extension of the idea of gender, first to material objects without life, and then to abstract terms and mental notions, the directing associations are weaker, and the mind is in a state of oscillation. It may be observed, however, that abstract nouns, or to speak more correctly, general terms, are usually included among the feminines, perhaps from a notion of pregnancy, the one term including a large aggregate of concrete ideas. There are indeed exceptions to this principle; for instance, in the large family of Latin words which have the suffix *or* (*honor*, *pudor*, &c.), but this variety is probably to be explained by the similarity of the termination to the masculine suffix *tor*. The French language has corrected this anomaly in *la pudeur*, &c. We have here probably an explanation of the principle by which in Greek a feminine article attached to what is commonly a masculine substantive gives it the power of a collective, as ιππος, m. "a horse," but ἡ ιππος, "the horse," that is "the cavalry;" ἡ καμηλος, "the body of camels." The same peculiarity belongs to the Arabic and Hebrew, and indeed is still preserved in a modern Semitic language, the Galla.

The mode of denoting gender is also deserving of consideration. One of the most direct methods would appear to be to assign names absolutely different to the male and female, that is, in those cases where the terms are used in their natural, not in their metaphorical sense. Thus we have in our own language *boy* and *girl*, *horse* and *mare*, *bull* and *cow*, &c. One of the defects of such a principle would be the want of a general rule by which to denote the gender in any new instance, and the consequent multiplication of terms. But independently of the advantages and disadvantages of this notation, there are good reasons for believing that in fact the distinction of sex was not originally denoted by an absolute difference of term. The word *man* for instance, in the oldest Teutonic language had the general meaning of a human being, like the Greek ανθρωπος, or Latin *homo*, and only gained the exclusive notion of a male when its derivative *mannisco* or *mensche* was formed to express the general idea. The German term *frau* again is now confined to the female, but there is found in nearly all the older dialects of the German a masculine so nearly identical (*frauha*, Gothic; *frô*, old high German; *froho*, old Saxon; *frea*, Anglo-Saxon) that the notion of the female can scarcely have been inherent in the word. Similar results would be given by an examination of the English word *maid*, the Latin *puer*, &c. In the animal kingdom the same confusion prevails. The Latin *ovis* is commonly feminine; and in fact our English term *ewe* may be indisputably proved to be the same word; still, in the earlier form of the Latin language, the word was also applied in the sense of *aries*. It occurs, for instance, in the name of the sacrifice *Suovetaurilia*, where the word *taurus* leads us to expect the idea of a *ram* in *ovis*, and of a boar in *sus*; and in fact ancient reliefs prove that the animals sacrificed at this festival were uncastrated males. The word *sus*, corresponding in ordinary signification, as also in form, to the English *sow*, is a parallel case. Indeed both Greek and Latin exhibit this very word as not confined to either sex. A long enumeration of similar instances, with the necessary proofs, would be out of place here. It will be sufficient to notice that the English terms *mare* and *hen* appear in other branches of the Teutonic language as representatives of the male. Lastly, those who attribute to these monosyllabic forms a distinct notion of gender will find it difficult to avoid the inference that if *gallus* for example, originally meant a *cock*, and not as is here maintained, a *fowl* generally, *gallina* included the notion of both sexes, a *female cock*. A more simple mode of denoting gender is by the addition of a special suffix. Thus the Latin termination *on*, like the Italian *one*, appears to have carried with it the idea of a man, as in the familiar cognomina *Nason*, *Capiton*, &c. Thus again, *leon*, "a lion," is in reality formed of two words, *le* or *li*, the simple name of the animal, and *on*, man or male. The form *li* (nom. λις) occurs in the Greek language as well as λεων; and moreover, if the name of the animal was thus monosyllabic, it is seen at once how natural it was to adopt it, as was in fact the case, for the hieroglyphical symbol, or at any rate for the Hebrew character of the letter *l*. The addition of the feminine suffix *ina* or *aina* to the same root *le* gave the female, *leaena*; and indeed the same suffix appears in *gallina*, *regina*, the Greek βασιλιννα, the German *königinn*, &c. Of the male suffix, other examples may be seen in *centurion-*, *caupon-*, *falcon-*, *pavon-*, &c.; the last of which may be compared with the Greek *ταω-ς*, and the English *pea-cock*. The most frequent suffix in the Greek language to denote the feminine is the syllable *σα*, as in *Φοινισσα*, *κιλισσα*, and the participles *τυπτοντσα*, the parent of *τυπτουσα*, *τυφθεντσα*, afterwards *τυφθεισα*. The same suffix is found in the Gothic, as *gaitsa*, *capra*; and in German, as *farre*, a bull, *färse*, a cow. Our own language too is familiar with what is probably the same suffix in *seamstr-ess*, *laundr-ess* (from *lavender-ess*). In the Greek language this suffix appears at times to have lost its sibilant, as was so common in that language. Hence the forms *βασιλε-ια*, *αξε-ια*, *τετυφυ-ια*, for *τετυφοτ-ια*.

In the Latin language a mere vowel *a*, but originally a long *a*, as is proved by the Sanscrit, by the oblique cases of the Latin first declension, and in old Latin even by the nominative, for the forms *aquilā*, *sanctā filiā*, &c., occur in the earliest poets, while the Greek too has not a few nominatives with a long *α*. But the forms *scriba*, *incola*, &c., with the numerous proper names, *Cinna*, *Sulla*, &c., prove that the notion of the female was not inherent in this declension; and probably the fact was that there co-existed in primeval Indo-European language two dialects, one preferring *a*, the other *o* (precisely as in our own island, there are the two forms *two* and *twa*, *who* and *wha*, *one* and *ane*); and secondly, that by a false refinement in language, an arbitrary distinction of gender was set up between them. The same argument of course applies to the Greek form *αγαθο-ς* and *αγαθα* or *αγαθη*, in which it must be carefully recollected that the sibilant at the end of *αγαθος* has nothing to do with the question, as it is simply the representative of the nominative case. It should also be recollected that the older Greek language abounds in the common adjectives, such as *ὁ* and *ἡ αθανατος*. Moreover the advocates of an original distinction of gender in the two first declensions have to explain the anomalies of *ἡ ὁδος*, &c., and the Latin *fagus*, &c. Again, that the Latin forms *bono-* and *bona-* were originally but dialectic varieties appears to be established by the consideration that nearly all derivatives from the second declension take an *a*, as *albare*, *aurare*, &c., a strange consequence of which is, that the Latin language is almost wholly deprived of a conjugation of verbs in *e* corresponding to the Greek *δουλε-ω*. It is another strange fact, that in Gothic the forms in *a* are masculine, those in *o* feminine.

Lastly, every language has the power of denoting gender by the addition of a distinct word, as in *jack-snipe*, *cock-sparrow*, *tom-cat*. This use of the names of men is seen in other languages besides our own. Thus the Anglo-Saxon employs *carl* for this purpose. In the German *täuberich gänserich*, it would be wrong, however tempting, to asume that the past *erich* is the prenomen; we should rather divide the words so as to give to *er* the notion of a male, and to *ich* that of a diminutive. Thus *täub-er-ich* is the "little-male-dove." Violent corruptions of this form exist in our tongue in *lark*, abbreviated from *laverock*, a term still used in Scotland; and *drake* from *andrake*, itself a corruption from *anat-er-ock*.

The suffix *ster* of our own language marks a female agent, and still preserves the sense in *spinster*. The words *bagster*, *webster*, *brewster*, refer to offices not ill-suited to the female, but they have now disappeared as appellatives, and are employed, in England at least, solely as surnames. The male terms which correspond to them are of course *baker*, *weaver*, *brewer*. It is in the Dutch that the best evidence exists to show that *ster* is truly a suffix to denote female agents.

Nothing has been said of suffixes to denote the neuter gender; simply because there exist, strictly speaking, no such suffixes. There are indeed appearances of such additions; first, in the Greek neuters *αγαθον*, and the Latin *bonum*; secondly, in the neuter pronouns of the Latin language terminating with a *d*, which correspond to an *s* in German and a *t* in English; as *quod*, *was*, *what*; *id*, *es*, *it*, &c. Of the first class it is enough perhaps to throw out a suspicion that the *m* and *d* (*s*, *t*) were originally part of the stem of the noun, and no case-ending.

In the Scandinavian languages, as now existing, the genders have a peculiar character, consisting of a neuter, if gender it can be called, and a common gender, which includes the masculine and feminine. By a strange accident, the definite and indefinite articles have here a common form, and are distinguished solely by their position. Thus the word *one* or *an*, as written by us, is represented by *en* m. or f., *et* n.; while the definite article, of the same form, but no way related to it, is attached as an enclitic. Thus we have in Danish for the common gender: *en mand*, "a man," *manden*, "the man;" *en quinde*, "a woman," *quinden*, "the woman," *en dag*, "a day," *dagen*, "the day;" and for the neuter, *et lam*, "a lamb," *lammet*, "the lamb;" *et ord*, "a word," *ordet*, "the word." The *en et* of the definite article may be compared with the forms *εν* of *εν-θεν*, *in* of the Latin *in-de*, and our own *it*.

GENEALOGY. [PEDIGREE.]

GE'NERA, in ancient Greek music, were of three kinds,—the Diatonic, Chromatic, and Enharmonic. [DIATONIC; CHROMATIC; ENHARMONIC.] These were subdivided into many species, which are enumerated by Gaudentius and Aristoxenus. "Indeed," says Sir J. Hawkins, "the representations of the genera and their species, as well by diagrams as in words, are almost as numerous as the writers on music." To that erudite historian of music we refer the reader who wishes for more information on a subject in which so few now take the slightest interest. The modern diatonic and chromatic genera, or scales, are probably much the same as, or nearly allied to, those of antiquity. Our Enharmonic is, practically,—at least on most instruments,—but a convenient evasion, the mere bestowal of two names on one and the same sound.

GENERAL, the title of the highest tank conferred on military officers. In all the states of Europe it indicates the commander-in-chief of the forces of the nation; the commander of an army or grand division, and also those who, under the latter, exercise his functions, with the particular designations of lieutenant general and major-general.

The origin of the title appears in the history of France, in which country it seems to have been conferred on the commander of the royal army about the middle of the 15th century, when something like a regular military force was first established in Europe. The kings were then considered as holding the chief command of the army by virtue of their birth; and, on appointing persons under them to exercise a general superintendence of the forces, they gave to such officers the title of *lieutenant-general*, in order to designate at the same time the extent of their duties and their dependence on the sovereign whom they represented. By a decree made in the year 1450, in the reign of Charles VII., John, count of Dunois, was so qualified; and the title of lieutenant-general, denoting the immediate commander-in-chief of an army, was long retained in the French service. In the course of time, by an abbreviation in language, the prefix of the title was omitted, and the term *general* alone was applied to persons holding such command.

Previously to the epoch above mentioned the title of Grand Sénéchal of France appears to have conferred the right of commanding the royal armies; but the dignity being hereditary in the counts of Anjou, when that province passed to the crown of England in the reign of Henry II., the right ceased, and the kings of France delegated their authority to noblemen chosen at pleasure. In 1218 Philip Augustus conferred the command on Mathieu de Montmorenci, the Constable of France; and the successors of that high office held it till the re-formation of the army in the reign of Charles VII.

It must be remarked, however, that at a period more early than that of the creation of lieutenant-generals under the sovereign, the title of captain-general had been conferred on certain officers with military jurisdiction over particular districts. This species of command is supposed to have been first instituted in 1349 by Philip of Valois, who placed Guy de Nêle, already Maréchal de France, over the district of Xaintonge; within which he was authorised to inspect the castles and fortified towns, and to superintend all the military affairs. The nature of the duty therefore seems to have resembled that of the general officers now appointed to particular divisions of this country and the colonies. But in 1635, that is, about eight years after the suppression of the post of constable of France, Louis XIII. gave the title of captain-general, for the army of Italy, to the Duke of Savoy; and this appointment was precisely that of commander-in-chief, since it placed the duke above the Maréchal de Créqui, who was previously at the head of the army.

It is about this time that the term lieutenant-general, in the sense which it now bears, first appears. For, according to Père Daniel, who quotes the history of Cardinal Richelieu for the fact, when the Prince of Condé was made commander-in-chief of the army destined against Spain, the Marquis de la Force was appointed his *lieutenant-general*, and M. de Feuquères held the same rank under the Duc de Longueville, who was to act with an army in Franche-Compté. We have here but one lieutenant-general for each army: but the writer above mentioned observes that, during the reign of Louis XIV., the armies of France being much more numerous than before, the officers were also greatly multiplied; and adds that, in 1704, there were more than sixty who had the title of lieutenant-general.

The title of captain general above mentioned must not be confounded with that which was created by Cardinal Richelieu, in 1656, in favour of the Marquis de Castelnaut: this officer was placed above the lieutenant-generals of the army, but was subordinate to the marshal of France, who commanded in chief; and it appears that some of the former having retired from the service in disgust, in consequence of the new appointment, the cardinal was obliged to appoint others in their places.

In the reign of Francis I. the title of colonel-general was instituted; and it was first in 1544 conferred on M. de Taix, with the command of all the infantry of the nation. The title existed however only to the time of Louis XIV., by whom it was abolished.

The English nation has nearly followed the practice of France in matters appertaining to the military service. Thus the lord high-constable and the lord-marshal of England, in former times, were at the head of the military establishments of the country; and when the first office was suppressed by Henry VIII. in 1521, the title of captain-general appears to have been adopted for the commander-in-chief. This title occurs in the list of the army which served at St. Quintin in 1557, of which list a copy is given by Grose from a MS. in the British Museum. From the same list it appears that a lieutenant-general for the whole army was immediately subordinate to the former; and that under the last was a general of horse, a captain-general of foot, with his lieutenant, and a serjeant-major (corresponding to a present major-general). But the title of captain-general probably did not long remain in use; for, in the list of the army raised by Elizabeth in 1588, the highest officer is styled lieutenant-general, the queen herself being probably considered as the commander-in-chief. In the army which, in 1620, it was proposed to raise for the recovery of the Palatinate, and in that raised by Charles I. in 1639, the commander is entitled the lord-general; a lieutenant-general appears as the second in command, and the third is designated sergeant-major-general. It was probably soon after this time that the last officer was called simply major-general; for we find that in 1656 Cromwell appointed twelve officers under that title to have civil and military jurisdiction over the counties of England. (Clarendon, b. 15).

It is evident, from the histories of the northern states, that the armies in that part of Europe have always been commanded nearly in the same manner as those of France and England. Sir James Turner, who wrote his 'Military Essayes' in 1670, states that in Germany, Denmark, and Sweden, the commander-in-chief was designated field-marshal, and that he had under him lieutenant-generals of the whole army, besides generals and major-generals of horse and foot. With respect to the first title, he considers it to have been granted, as a more honourable distinction than that of lieutenant-general, only within about fifty years from his time: and he appears to ascribe the introduction of it to the king of Sweden (Gustavus Adolphus), who, when he invaded Poland, thought fit to gratify some of his generals by designating them lieutenant-field-marshals. ('Pallas Armata,' ch. 13.) From that time, both in Germany and Great Britain, such title, omitting the word lieutenant, has been considered the highest in the army.

In France, during the reign of Louis XIV., and perhaps at an earlier time, the naval commander immediately below the rank of vice-admiral was entitled lieutenant-general. A similar designation seems to have been early employed in the English service, for in the time of Queen Elizabeth the commander of a squadron was called the *general;* and, as late as the time of the Commonwealth, a joint commission of admiral and general was given to Blake and Montague, though the expedition on which the fleet was sent was confined to an object purely naval.

The administration of military affairs in the great nations of Europe becoming highly complicated during the eighteenth century, the commanders-in-chief, even when not actually on the field of battle, found themselves fully occupied with the higher departments of the service; and it became indispensable that the number of subordinate generals should be increased, in order that all the steps which were to be taken for the immediate security of the armies, and for the acquisition of the necessary supplies, might be duly superintended by responsible officers. The division of an army into brigades and divisions for the purpose of organisation and also of occupying important positions or of obtaining subsistence, led also to the appointment of several distinct commanders, each of whom required his own particular staff; and this circumstance, added to the necessity of having a number of officers prepared at once to assume the command of troops when circumstances should require it, will explain why military men holding the rank of general appear now to be so numerous.

In the British service there are about 60 full generals, and 100 lieutenant- and 160 major-generals; of this number many command particular regiments as colonels, or hold military governments in the country and colonies; many of them have only local rank; and many have retired from the service, retaining the title, but without receiving the pay or being qualified for obtaining any progressive promotion.

The adjutant- and quarter-master-general are officers of the staff. [STAFF.]

In the English army, a general of division is either a major or lieutenant-general placed in command of a division of an army in the field, and a brigadier-general is either a colonel or major-general in command of a brigade—the titles only lasting while the officer is actually holding the command. In the French service however, general de brigade and general de division are permanent ranks answering to our major-general and lieutenant-general.

The first notice of a commander of the artillery occurs in the time of Richard III.: this officer was designated simply master of the ordnance till 1603, when the Earl of Devon was dignified with the title of General. The head of this department was, till lately, styled master general of the ordnance. The office is now abolished.

GENERAL ASSEMBLY OF THE CHURCH OF SCOTLAND. This is the Scottish ecclesiastical parliament; it is a representative, legislative, and judicial body, which differs essentially in its constitution from the Convocation of the English church [CONVOCATION], in being composed of representatives of the laity, as well as of the clergy; and, therefore (like the British House of Commons), may be considered as a delegation from its constituency, the church. [CHURCH.]

The General Assembly consists of representatives from the various presbyteries, of which there are 84; of lay elders sent from Edinburgh and many other royal burghs, and from the universities (the representatives of the universities may be either ministers or elders);—and one minister and one elder to represent the churches in India in connection with the church of Scotland. The kirk of Scotland in 1859 had 1023 parishes, with 1194 ministers.

The General Assembly meets annually, in the month of May, in Edinburgh. The session lasts only ten days; but special business not decided within the period of the session may be referred to a commission, which is, in fact, the Assembly under another name: the commission can hold quarterly meetings. The speaker, or president of the assembly, is called moderator: he is chosen annually, and is, in modern times, a clergyman, it being a rule that the moderator should preach a sermon before the opening of the Assembly; but laymen have occasionally filled the chair.

Each parish in Scotland has its kirk session, composed of the minister and lay elders of the parish, which manages the parochial business. From the decision of the kirk session there is an appeal to the presbytery in which the parish lies. Each presbytery is composed of the ministers and elders of a certain number of parishes; but the presbyteries vary considerably in the number of parishes of which they are formed. A higher court, called a synod, (of these there are sixteen) is composed of two or more presbyteries. From the decision of a synod an appeal lies to the General Assembly, whose decision is final. The functions of the Assembly are analogous to a combination of the functions of both houses of parliament. Its members speak and vote; it judges all matters connected with the government of the church; and it can proceed judicially against any member of the church, clerical or laical, for alleged impropriety or inconsistency of conduct or doctrine.

The connection of the Church of Scotland with the State is indicated in the General Assembly by the presence of a functionary, who, under the title of lord-high-commissioner, represents the king or queen. The Scottish church however does not recognise the king or queen as head of the church, but as head of the state, with which the church is allied, for purposes of protection and civil authority. The lord-high-commissioner has no voice in the assembly; business is not necessarily interrupted by his absence; and his presence merely implies the sanction of the civil authority. On the conclusion of the session of the General Assembly, the moderator, after mentioning the day in the following year on which the Assembly meets again, dissolves the meeting in the name of the Lord Jesus Christ, the head of the church (sometimes the words 'the only head' are used), and then the lord-high-commissioner adds the sanction of the civil authority by appointing in the name of the king or queen the Assembly to meet on the day named by the moderator.

The Free Church, since the disruption, has held a General Assembly of its own, about the same time as that of the established Church, but it is not recognised by the government more than the assemblies of other sects for the internal management of their own ecclesiastical affairs.

GENERAL ISSUE. [PLEADING.]

GENERALISSIMO, the commander-in-chief of an army which consists of two or more grand divisions under separate commanders. The title is said by Balzac to have been first assumed by Cardinal Richelieu, when he led a French army into Italy, and it has been since occasionally given to officers at the head of armies on the continent, but it has never been adopted in this country.

GE'NERATING FUNCTIONS. The term *generating function* is a name given by Laplace to any function of x, considered with reference to the coefficients of its expansion in powers of x, as follows: If

$$\phi x = \psi 0 + \psi 1 \,.\, x + \psi 2 \,.\, x^2 + \ldots + \psi n \,.\, x^n + \ldots.$$

then ϕx is the generating function of ψn. Thus, the generating function of n is $x \div (1-x)^2$, since the coefficient of x^n in the expansion of the preceding is n.

The theory of generating functions was investigated by Laplace, and it may be found in his 'Théorie des Probabilités,' or in Lacroix, 'Treatise on the Differential Calculus' (in the third volume of the quarto edition), in the Appendix to the Cambridge translation of Lacroix, or in the article on 'Probability' in the 'Encyclopædia Metropolitana.' Its principal use is in the solution of equations of differences, and in the deduction of theorems connected with that subject.

GE'NESIS, THE BOOK OF, is the first of the five books of Moses, and derives its name from the principal event recorded in it, namely, the creation of the world and the human race, which in the Septuagint Greek translation is expressed by the word *Genesis* (Γένεσις), "creation," or "production." In the original Hebrew it is named, according to the usual custom, from the first word in the book, *Bereshith* (בְּרֵאשִׁית), "In the beginning." It is also the first book of the Pentateuch, so called from the Greek πεντε, 'five,' and τευχος, and 'implement' or 'volume;' that is, the five-fold volume, which comprises the five books of Moses,—Genesis, Exodus, Leviticus, Numbers, and Deuteronomy,—and which down to the present time form one continuous rolled volume in the Hebrew manuscripts.

It has been thought by many critics that the book of Genesis was not written by Moses. There are some passages in it which evidently could not have been the composition of Moses, since they refer to events which happened after his death. See c. xiii. 18, c. xxiii. 2, and c. xiv. 14, where Hebron and Dan are mentioned, which, we learn from other parts of the Bible, had different names in the time of Moses. See also Gen. xxxvi. 31, where an allusion is made to the kings of Israel, and a list is given (31—43) of the princes of Edom, which is the same as the list given in Chronicles i., c. i. 43—54. But these and similar passages might easily have been inserted in later times. Dr. Graves, in his 'Lectures on the Pentateuch,' and Faber, in his 'Horæ Mosaicæ,' show that there is no other period in the history of the Jews to which its composition can be so well referred. The preface to the first volume of the last edition of Rosenmüller's 'Scholia in Vetus Testament,' contains a fair view of the controversy, in which he gives many reasons for relinquishing the opinion he formerly held, that the book of Genesis was not written by Moses.

Supposing Moses to have been the author, it becomes an interesting question to ascertain in what manner Moses was enabled to give a faithful history of events which happened so many centuries before his own age. The book must have been composed in one of three ways: 1st, by immediate revelation of every circumstance from God; 2nd, by a collection of ancient traditions; or 3rd, from former documents. The first supposition is generally abandoned in the present day by all theologians, with the exception of those who believe in the verbal inspiration of the Scriptures. The second, which is a common opinion amongst theologians in this country, would not injure the credibility of the book: since Lamech, the father of Noah, was contemporary with Adam; Shem, the son of Noah, lived in the time of Abraham; his son Isaac was contemporary with Joseph; and some of the contemporaries of Joseph might have known Moses; so that few persons were required for the transmission of the traditions. The third opinion is the one generally received by the German theologians of the present day: that they were few, is most probable, but the existence of written documents anterior to the time of Moses is unquestionable. In Genesis xxvii. the blessing of Isaac on his sons, and in xlix. the dying address of Jacob, are both apparently given verbatim. This opinion is strengthened by the fact that, in other books of the Pentateuch, reference is made to pre-existing sources. In Numbers xxi. 14, there is an avowed quotation, "It is said in the book of the wars of the Lord," &c.; and in xxiii. and xxiv. are given the hymns or parables of Balaam in his own words. This does not detract from, but rather adds to, the belief that the books were the inspired compositions of Moses; for though he may have used such pre-existing documents, and though his knowledge of many of the events might have been derived from contemporaries,—as, for instance, the Egyptian relation of the history of Joseph,—inspiration was not less necessary to enable him to distinguish the true from the false, and, while it was not needed in the case of the outward facts of Joseph's life and adventures, without it he could not have developed the scope of the mystery of Providence in those events as affecting the whole remaining history of the Hebrew nation. For a further investigation of this point, see Turner's 'Companion to the Book of Genesis,' New York, 1841. As to the attempts to prove a multiplicity of authorities from the designation of the Deity by different names,—as Elohim, God; Jehovah, Lord; and Jehovah-Elohim, Lord-God,—Hengstenberg, in his 'Authentie des Pentateuches,' has proved that the variation is always adapted to the sense of the passage in which the writer has used it, and never arbitrarily or uncertainly. Ranke ('Untersuchungen über der Pentateuch,' 1840), Dreschler ('Die Einheit und Aechtheit der Genesis,' 1838), and Mr. Turner, have taken the same view, and their works contain disquisitions on these various significations, by which they endeavour successfully to establish grounds of their hypothesis.

Objections have likewise been urged against the account of the Creation in the book of Genesis, as not agreeing with the facts of geology and natural history. These have been met by Dr. Pye Smith ('Geology and Scripture'), Dr. Redford ('Holy Scripture Verified'), Hugh Miller ('Footprints of the Creator'), and others, to whose works we refer the reader.

The chronology of the book of Genesis has occasioned great difficulty. This arises from the difference of the Hebrew text from the Septuagint. According to the Hebrew text, the Deluge happened A.M. 1656; according to the Septuagint, A.M. 2262; the former giving B.C. 4004, and the latter B.C. 5411, as the epoch of the Creation. Dr. Hales, with many other critics, considers the dates of the Septuagint to be more in accordance with profane history and with the various events related in the first chapters of Genesis. Our limits prevent us from giving an account of the controversy; we can only refer to the arguments in Dr. Hales' 'Analysis of Chronology,' vol. i. 273–303, and Clinton's 'Fasti Hellenici,' vol. i. pp. 283–301, the latter of whom defends the chronology of the Hebrew text, and observes, with much justice, that there does not appear any sufficient reason for inducing the Jews to change the numbers, while the translators of the Septuagint were naturally anxious to make the epoch of the Creation more conformable with the high pretensions of the Egyptians and Chaldæans. From the Deluge to the common date of the birth of Abraham, the Hebrew text gives 292 years, the Septuagint 1072. This date is given on the authority of Gen. xi. 26: "And Zerah lived 70 years, and begat Abram, Nahor, and Haran." But there is sufficient reason for believing that Abraham was not born till 60 years afterwards, and that his name is only placed first on the catalogue on account of his celebrity, not because he was the first-born. Adding 60 years to the former numbers, we obtain the birth of Abraham according to the Hebrew text, A.M. 2008, or B.C. 1996; according to the Septuagint, as corrected by Dr. Hales and Mr. Clinton, A.M. 3258, or B.C. 2153. Having obtained the birth of Abraham, there is no great difficulty in ascertaining the dates of the principal events that follow. The following table is abridged from Clinton's 'Fasti Hellenici;' the dates are reckoned from the birth of Abraham:—

Birth of Abraham in 130th year of Zerah. Gen. xi. 32, xii. 3–5, compared with Acts vii. 4.

10. Birth of Sarah, ten years younger than Abraham. Gen. xvii. 17.
75. The call of Abraham. Gen. xii. 1–4.
86. Birth of Ishmael. Gen. xvi. 16.
100. Birth of Isaac. Gen. xvii. 17.
137. Death of Sarah, at the age of 127. Gen. xxiii. 1, 2.
140. Marriage of Isaac, at the age of 40. Gen. xxv. 20.
160. Birth of Esau and Jacob. Gen. xxv. 26.
175. Death of Abraham. Gen. xxv. 7, 8.
237. Jacob goes to Haran at the age of 77.
257. Jacob returns to Canaan. Gen. xxxi. 41.
268. Joseph, at the age of 17, sold into Egypt. Gen. xxxvii. 2.
280. Death of Isaac, at the age of 180. Gen. xxxv. 28.
281. Joseph, at the age of 30, governor of Egypt. Gen. xli. 46.
290. Jacob, at the age of 130, goes into Egypt. Gen. xlvii. 9.
307. Death of Jacob, at the age of 147. Gen. xlvii. 28.
360. Death of Joseph, at the age of 110. Gen. l. 26.

The following passages are supposed by most Christian divines to be prophecies relating to Christ:—iii. 15; xii. 3; xviii. 18; xxii. 18; xxvi. 4; xxviii. 14; xlix. 10.

(Eichhorn's *Einleitung in's Alte Testament*; Augusti's *Grundriss einer historisch-kritischen Einleitung in's Alte Testament*; Faber's *Horæ Mosaicæ*; Graves *On the Pentateuch*; Rosenmüller's *Scholia*; Holden's *Dissertation on the Fall of Man*; Horne's *Introduction to the Scriptures*; Von Bohlen, *Die Genesis übersucht, mit Aumerkkungen*, 1835; Tush, *Kommentar über die Genesis*, 1838.)

GENEVA; GIN; HOLLANDS. There is a confusion in the popular meaning of the names of these three kinds of distilled liquor. Geneva is frequently confounded with gin. It is, however, a fermented liquor, which bears the same relation to gin as wine does to any distilled spirit. It is procured by the fermentation of the berries of the *Juniperus communis*. These berries consist of a peculiar saccharine principle (which exists to the amount of about 33 per cent. along with acetate of lime), and a volatile oil, which is contained in peculiar cells lying close to the seeds; as the oil assumes a resinous state in old berries, these cells may be easily seen in such specimens. The green one-year-old berries contain much more volatile oil, and are to be preferred to the ripe berries. The oil rarely exceeds one per cent. From the quantity of sugar which they contain the berries can easily be caused to ferment and yield a spirit, or vinegar may be made from them. Geneva is a very powerfully stimulating liquor, containing a large proportion of alcohol. The volatile oil having a special action on the kidneys renders it the most proper cordial in cases of dropsy from debility, or even connected with diseased heart, when the system requires support. The usual acceptation of geneva as a beverage is incorrect; nothing deserving of the name is sold in the spirit-shops of this country.

There appears to be no real difference between the so-called *Geneva* and *Hollands*; indeed these two names, as well as *Hollands Gin*, are now only different designations for the same liquid; but originally, as just observed, Geneva (not named from the Swiss city, but from the French name, *genièvre*, of the juniper), was a different liquid. Hollands, or Hollands geneva, or Hollands gin, is a kind of corn-spirit, which was originally wholly imported from Holland. The best kinds now made are those of Schiedam, Rotterdam, and Weesoppe, by various distillers, each of whom has his own peculiar process. Strasburg turpentine, fennel seeds, oil of fennel, and hops are used, as well as juniper, as flavouring ingredients; but it is supposed that the superiority of Hollands geneva over English gin depends rather on some peculiar mode of manufacture than on the ingredients employed, and on the fact that it becomes *aged*, or *mellowed*, or *creamed*, by remaining some time in bond before use. Some of the English rectifiers endeavour to produce a spirit exactly like Hollands; but a difference can always be detected by good judges. Pure Hollands have less acidity than any other spirit in common use. Concerning the more familiar liquid, *gin*, this name was an abbreviation of *Geneva*, and was adopted when English rectifiers began to make a liquid that might share the favour with which Hollands geneva was regarded. English gin, in the present day, consists of plain corn spirit, flavoured with oil of turpentine, and with a small quantity of other substances. Juniper may possibly be an essential element in Hollands geneva, but it is not in English gin. Each rectifier has a recipe of his own, which he does not divulge; and hence the difference in flavour between Booths', Hodges', Smith's, Nicholson's, Bristol, Plymouth, and other kinds of gin. Of all these it can scarcely be said that one is better than another, only that they differ, as one kind of London porter differs from another. Different kinds of gin have the plain-gin flavour, the Hollands flavour, the whiskey flavour, the smokey flavour, &c.; some are intended to present the qualities of fulness or richness, others piquancy or biting, &c.; and all these differences depend on the vegetable substances distilled with or added to the crude spirit—such as sugar, juniper, bitter almonds, turpentine, creosote, lemon, cardamoms, carraways, cassia, garlic, Canada balsam, Strasburg turpentine, horse-radish, grains of paradise, cayenne pepper, and various other berries, seeds, fruits, herbs, &c. Sometimes such chemical agents as sulphate of zinc, caustic potash, and sulphuric acid, are added; but this is usually for some fraudulent purpose. It is believed that London gin, *as retailed*, is more frequently adulterated than any other; because there is a taste in the metropolis for *sweetened* gin; and the addition of sugar masks the taste of some strong substance which has been added to facilitate a large dilution with water.

The processes of manufacturing these various kinds of spirit are described under DISTILLERY.

The importation of geneva, so called in the official returns, has varied in the last fifteen years from 130,000 to 430,000 gallons per annum; but there are other kinds, called "other foreign and colonial spirits," distinct from geneva, rum, and brandy, of which quantities have been imported varying from 30,000 to 1,100,000 gallons annually, and which are probably varieties of corn-spirit. This last-named entry has rapidly increased within the last few years. The computed real value of the geneva and corn-spirit imported in 1858 was about 130,000*l.* The British spirit charged with home duty, most of which is either gin or whiskey, has varied from 20,000,000 to 26,000,000 gallons yearly in the last few years. The difference between gin and whiskey, chemically and commercially, is noticed under DISTILLERY.

GENII, called in the East *Ginn* or *Djinn*, are supposed to be a race of beings created from fire, capable of assuming any form and becoming invisible at pleasure. All Moslems are obliged to believe in their existence, since they are said in the Koran (c. vi.) to be created by God. It is imagined that they inhabited this world many ages before man was created, and were governed by forty successive monarchs of the name of Solomon, the last of whom was called Gân Ebn Gân, and that from him they derived their name. It is also said that they frequently rebelled against God, who at length deprived them of their possessions and gave them to man. We learn from the Koran (c. 72) that many of these wicked spirits were converted by hearing Mohammed reading a portion of it, and that those who continue unbelievers (called, in c. 27, *Ifrit*) will be condemned to the fires of hell. They are believed to take great interest in human affairs, and to be the authors of much happiness and misery to mankind. (An interesting account of the superstitions of the modern Arabs respecting Genii is given in Lane's 'Modern Egyptians.') The belief in such an intermediary class of beings between divinity and humanity has been very extensive. The Greeks had their *δαίμονες*; the Romans their Genii [GENIUS]; the Chinese have their good and evil beings, and every town or province chooses one for its protector, to whom the governor prays, on his admittance to office, for support and assistance in his charge; and the Africans have their fetishes. It must be admitted, however, that none are so fanciful and poetical as the genii of the orientals.

The Roman genii are represented in works of art as winged figures; they are frequently figured contending in chariot races: in friezes in the British Museum their chariots are drawn by dogs, but they often are seen driving horses. Genii are commonly introduced by sculptors on monuments, &c.; sometimes they carry a cornucopia; at others they support the portrait of the deceased, or bear his armour, &c.

GENITIVE. [ABLATIVE CASE.]

GENIUS, in its original acceptation, denoted the tutelary god or dæmon which, according to an ancient and common superstition, was allotted to every individual at his birth, to guide and rule him during life, to preside over his fortunes and destiny, and eventually to lead him from existence; and it was supposed that the variety observable in the characters and capacities of different men was dependent upon the higher or lower nature of their attendant genii. Afterwards the word came to signify the disposition itself, without reference to its supposed cause; and lastly, in modern times it has been employed, in a restricted but peculiar sense, to designate either that high mental pre-eminence which is occasionally found in a few individuals, or, by a metonymy, the person possessed of such rare excellence.

Like every thing else that is truly beautiful and great, Genius has in it a something undefinable; and hence the variety of notions as to its origin and nature, in all of which there is and must be something deficient. Dr. Johnson's definition ('Life of Cowley,') is this: "The true genius is a mind of large general powers accidentally determined in some particular direction." Generally it is understood to be the perfection of human intelligence. And as this consists in the highest possible activity of the mental energies, genius is essentially creative, and all its productions are indelibly stamped with the impress of originality and grandeur. It is at once a law and a model to itself; it produces what has never before been accomplished, and which all, in all ages, are constrained to admire. It receives therefore its impulse from enthusiasm, for nothing great can be accomplished without that enthusiasm which is enkindled by some dominant idea, to which all else is made subordinate and postponed; and its chief faculties are the reason and the imagination, which alone are inventive and productive.

But according as one or other of these faculties predominates, genius becomes either scientific, artistic, or poetic. In the first case it seizes at once those hidden affinities which otherwise do not reveal themselves, except to the most patient and rigorous application; and as it were intuitively recognising in phenomena the unalterable and eternal, it produces truth. In the two latter, seeking to exhibit its own ideal in due and appropriate forms, it realises the infinite under finite types, and so creates the beautiful.

But even the most eminent genius must duly form and develope itself by a careful contemplation of the beautiful and true which the great geniuses of past time may have created and discovered. It is by looking exclusively to this circumstance, that those who deny any original inequality among men have been led to maintain that what is called genius is simply a result of education and culture; while on the other hand an equally partial consideration of those extraordinary powers which have occasionally been exhibited in totally uneducated minds, and under the most unfavourable circumstances, has deceived the zealous partisans of original genius.

In active life the grand and ambitious designs of successful statesmen and conquerors are often ascribed to genius, but they belong more properly to the energy of the will than to that of the intellect, to force of character rather than to power of mind.

The phrase "universal genius," in order to be legitimate, requires to be limited in one or other of its terms. When applied to a Fontenelle we must restrict the signification of genius to the power and capacities of the human mind in general; and it is only by confining the term universal to all the subordinate branches either of art or science, that it is even allowable to ascribe it to the genius of a Shakspere, a Michel Angelo, or a Leibnitz.

Genius and fancy are often confounded: the latter is undeniably a pre-eminent capacity, but it exerts itself rather to imitate than to invent, and is devoid of all enthusiasm.

GENOUILLÈRE. This is the term applied in fortification to that portion of the interior slope of the parapet, which is below the sill of the embrasure and in front of and covering the gun-carriage.

GENTIA'NA LU'TEA, a perennial plant, common in the mountainous and sub-alpine districts of Switzerland, Germany, &c. Though the whole plant is bitter, yet as this property is most concentrated in the root, that part only is officinal. The root should be taken up in autumn, and is best when the plant is only one year old. It is generally cylindrical, often an inch thick at the summit, but below rather branched, of a dark or brown colour externally; internally fleshy and yellow. In commerce it is met with in pieces, cut longitudinally, from six inches to a foot in length. A transverse section displays three distinct circles. The greater portion is procured from Germany; the specimens from Switzerland are generally thicker and darker coloured.

When fresh it has some smell, which is almost entirely lost by drying. The taste is at first somewhat sweet, then purely and strongly bitter. According to the analysis of Henry and Caventou, it contains a principle termed Gentianin, which is crystallisable; a volatile odorous principle, a greenish fixed oil, a free organic acid, uncrystallisable sugar, gum, colouring matter, &c. The oil is in very minute proportion; three *cwts.* yield only half a drachm of oil. The so-called gentianin consists of two distinct principles: one tasteless and crystalline, *gentisin* or *gentisic acid*, the other bitter *gentianite*.

Owing to its saccharine matter it soon moulds in a damp place, and should therefore be kept in a dry airy situation. From the abundance of the sugar, it is easily susceptible of fermentation, and from it is distilled a spirit, called Enziangeist, or "bitter snaps," much employed by the peasants on the Swiss Alps to fortify the system against the fogs and damps of these lofty regions. Strangers should be sparing in the use of this, as it contains a narcotic principle in addition to the spirit.

Yellow gentian-root is often confounded with the roots of other species of this genus, a circumstance attended with no bad consequences, but unfortunately roots of very poisonous plants, growing in the same locality, are often taken up instead of the proper one; these are, the Veratrum album (white hellebore), the leaves of which resemble those of gentian in their peculiar venation, but are alternate, while those of gentian are opposite—the root is very different, and besides this, it contains Veretria; and the Atropa Belladonna (deadly nightshade), which, besides differences in the physical characters, is devoid of the peculiar bitter of gentian, and acquires a bluish-black colour from tincture of iodine. The roots of Aconitum Lycoctonum and Ranunculus Thora are occasionally confounded with gentian-root.

Gentian-root is a pure and excellent bitter tonic, useful in all cases of debility, whether of the stomach only, or of the system generally. It possesses facilities, from not being decomposed, of being administered along with many metallic salts. It yields its properties to water, particularly when warm, to alcohol, and to wine. The simple infusion, and not the compound, of the 'London Pharmacopœia' should be employed, when any salts of iron are prescribed in the same formula. The extract is an eligible means of giving bulk, when several antispasmodic remedies, of which the dose is minute, are to be made into pills, such as oxide of zinc, protosulphate of iron, or extract of aconite. In the West Indies a preparation of gentian is used daily before meals, to give tone to the languid stomach. Stoughton's elixir, which is what is commonly used for this purpose, is only a quackish imitation of the compound tincture of gentian of the Pharmacopœia.

In the East Indies several species are used as bitter tonics. The Chirayita, or Chiretta, in the form of a cold infusion, is much prized for its tonic and febrifugal virtues. Guibourt contends that this plant is the Calamus aromaticus of the ancients, an opinion from which Dr. Royle dissents. ('Flora of the Himalaya,' p. 277.)

GENTIANIC ACID ($C_{22}H_{10}O_{10}$?); *Gentianin*; a crystalline acid extracted from the root of the *Gentiana lutea*. It is very slightly soluble in water, little more so in ether, but readily soluble in boiling alcohol. It does not redden litmus. Acted upon by nitric acid, it gives nitro-gentianic acid ($C_{22}H_8(NO_4)_2O_{10} + 2Aq.$).

GENTIANIN. [GENTIANIC ACID.]

GENTLEMAN, a corruption of *gentilhomme*, our Saxon ancestors having very early substituted "mon," or "man," for the corresponding term of the Norman-French, from which they originally received the term. Some form of this word (a compound of *gentilis* and *homo*) is found in all the Romance languages (*entil-homme* in French, *gentiluomo* in Italian, and *gentil-hombre* in Spanish), and it is undoubtedly one of the many traces of the great influence which the laws and polity of Rome exercised upon modern society and civilisation.

In the earliest form of the Roman constitution the populus, or ruling portion of the community, was divided into gentes, who were united by a common name, and the performance of certain sacred rights. Each gens was again subdivided into several familiæ, distinguished by a surname in addition to the common gentile appellation. Thus, the gens Cornelia comprised the families of the Scipiones, the Lentuli, the Syllæ, &c. Now, in default of the Agnati, or of heirs in the male line, the property of the family reverted, not to the whole populus, in whom, of strict right, the sovereignty lay, but to the gens to whom it had transferred its rights.

This right of reversionary succession, especially in the case of usufructuary possessions of the public lands, being the most valuable and important privilege of the patricians, was brought prominently forward in the quarrels between the nobles and the plebeians, and the phrase *gentem habere* (Livy, x. 8) is often employed as distinctive of the former. Afterwards, when the members of the plebs obtained the right of intermarriage with the patrician families, and an access to the honours of the state, which conferred the *jus imaginum*, or nobility, they also received the rights and privilege of *gentes*. To be admitted into a *gens*, became henceforward equivalent to a patent of nobility in modern times, and *gentilis* is accordingly widely defined by Cicero ('Top.' 6) as denoting those who were of the same name and stock, free-born, in the full enjoyment of all the rights of citizenship, and whose ancestors were always free. Hence, also, in an opposite sense, "*sine gente*" is employed by Horace ('Sat.' ii., v. 15) and Suetonius ('Tib.' 1) for ignobly born and of servile parentage.

This privilege of succession, which was called *jus gentilitatis*, or simply *gentilitas* (Cic., 'De Oratore,' i. 38), and formed one of the enactments of the Twelve Tables, was gradually undermined by the encroachments of the prætors on the civil law, and finally disappeared (Gaius, iii. 25); but the name has survived in all the languages of Western Europe.

According to Selden ('Titles of Honour,' p. 852), "a gentleman is one that either, from the blood of his ancestors, or the favour of his soveraigne, or of those that have the vertue of soveraigntie in them, or from his own vertue, employment, or otherwise, according to the customes of honour in his countrie, is ennobled, made gentile, or so raised to an eminencie above the multitude, that by those lawes and customes he be truly nobilis, or noble, whether he have any title, or not, fixed besides on him." That the word was formerly employed in this extensive signification is clear from a patent of Richard II., by which one John de Kingston is received into the estate of a gentleman and created an esquire ("Nous lui avons resceivez en l'estate de gentilhome et lui fait esquier"); and from another of Henry VI., who there, by the term "nobilitamus," creates one Bernard Angevin, a Bourdelois, a gentleman. And, according to Smith ('De Rep. Ang.,' lib. i., c. 20, 21), under the denomination of gentleman are comprised all above yeomen, whereby noblemen are truly called gentlemen.

In a narrower sense, a gentleman is generally defined to be "one who, without any title, bears a coat of arms, or whose ancestors have been freemen; and by the coat that a gentleman giveth, he is known to be, or not, descended from those of his name that lived many hundred years since." (Jacobs' 'Law Dictionary.') There is also said to be a gentleman by office and in reputation, as well as those that are born such (2 'Inst.' 668); and, according to Blackstone, quoting Sir Thomas Smith (1 'Comm.,' p. 406), "Whosoever studieth the laws of the realm, who studieth in the universities, who professeth the liberal sciences, and (to be short) who can live idly and without manual labour, and well bear the port, charge, and countenance of a gentleman, he shall be called master, and taken for a gentleman."

The learned author must have been somewhat puzzled with his definition of a gentleman, as understood in his time. Having defined a gentleman to be one who studieth the laws, &c., he adds (to be short) that he who can live idly and bear the port, &c., of a gentleman, is a gentleman; that is, if he can live idly, and if he can also do as a gentleman does (it not being said what this is), he is a gentleman. Perhaps a definition of the term, as now used, would not be easily made; it being extended by the courtesy of modern manners to many who do not come within the ancient acceptation of the term, and denied by public opinion to many whose rank and wealth do not make up for the want of other qualifications.

GENUS, in Physics, signifies a multitude or class of objects possessing some common quality or qualities. In logic it denotes the material part of the definition.

When we direct our attention to a particular object, we discover under its apparent unity a great variety of characters and qualities; and, upon an examination of several objects, we observe many points of agreement and difference between them. By the power which we possess of concentrating our faculties, we are enabled to consider these mutual relations and resemblances without any regard to their differences: we, as it were, draw the one away from the other; in short, we abstract them.

Now, by abstraction, we may either confine our view to a quality inherent in some object independently of that object; or else, neglecting the many points of disagreement which exist between a number of objects, we may seize upon the qualities that belong to all in common, in order to combine them into a single idea. In the former case the notion is simply abstract; in the latter it is abstract and general; and the multitude of objects to which we apply the general notion or common term constitutes a *genus*.

In this operation we may proceed continually by neglecting in succession a greater number of differences, and comprising under the common denomination fewer points of agreement and resemblance. In this manner we form a series of notions or genera of higher and lower order, until we ultimately arrive at the highest possible—that of *being*. In this co-ordination of genera, every intermediate genus is called a subaltern genus or species, being such in respect of different other terms; for that of which a higher genus is predicated is called a species, while relatively to all lower species it is itself a genus. Lastly, that which is not contained under any higher, is called the *summum genus*, and that under which individuals only are comprised is usually called the *infima species*.

These general notions and genera are the principles of classification and arrangement, and without them the knowledge of facts and nature itself would be, if not absolutely impossible, at best a confused mass of conceptions and objects without beauty, order, or coherence. But at the same time that we thus admit the utility of such general notions, we must remember that they are purely relative to human science and its objects; that even as such they are imperfect, and very far from conveying an adequate expression of the truth of nature, wherein there is nothing really corresponding to them, but only a something in the individual objects from which we derive them, which not only is the cause and the occasion of our forming them, but also transferring to them, as it were, a part of its own verity and existence, justifies us in according to them our confidence in science and action.

GEOCENTRIC (having the earth as centre), a term applied to the place of a planet, as seen from the centre of the earth, in opposition to its *heliocentric* place, as seen from the centre of the sun. [PARALLAX.]

GEO'DESY is that branch of applied mathematics which determines the figures and areas of large portions of the earth's surface, the general figure of the earth, and the variations of the intensity of gravity in different regions, by means of direct observation and measurement.

Some of the ancient philosophers, who lived several centuries before the Christian era, were acquainted with the nearly spherical form of the globe, and even devised methods for measuring approximately a meridional circumference. [ERATOSTHENES, in BIOG. DIV.] The Arabs long afterwards pursued the same object, and the Caliph Almamoun, in A.D. 814, ordered the measurement of a degree in the plains of Mesopotamia, an example which, after another long interval, was imitated by Snellius in Holland, Norwood in England, and by several French and Spanish mathematicians. Richer observed a variation in the length of the seconds' pendulum when sent to Cayenne by the French Academy of Sciences, the true cause of which phenomenon was explained by Newton; for the centrifugal force arising from the earth's rotation round its axis in twenty-four hours is directly opposed to the force of gravity at the equator, and in other latitudes the part of this force which acts in the direction of the plumb-line is nearly proportional to the square of the cosine of the latitude. He has also proved in his 'Principia' that a uniform fluid spheroid, in which the ratio of the centrifugal force to the attraction at the surface was the same as in the earth, would be in equilibrium when the axis of revolution was less than the equatorial diameter by 1-230th of the latter. From that time measurements have been undertaken under the directions of the various governments of Europe, to determine if the globe were really flattened at the poles, and also for the purpose of forming exact maps with respect to the latitude, longitude, and altitude, above the level of the sea, of places in their respective dominions; and lastly, the French have deduced their legal metre of length from the measurement of a particular meridian arc. Jacobi has lately shown that a revolving fluid ellipsoid, having three unequal axes, may also present a surface of equilibrium.

The result of so many geodetic enterprises has not been as successful as could be wished. Some of the earliest attempts by the French were faulty in computation, and gave results directly contrary to Newton's theory, and some able mathematicians of that day appear to have been misled by a feeling akin to envy, to the extent of supporting these false conclusions by plausible reasonings. The error of that survey has been since discovered, and all the methods which have been employed in the numerous trials undertaken in this and the last century agree in proving that the polar axis of the earth is shorter than the equatorial by about 1-300th; but they have served at the same time to demonstrate that the earth is not a spheroid, that it is not a solid of revolution, and that the figures of the northern and southern hemispheres are dissimilar. Hence if we suppose a solid of revolution having its axis in the same direction as that of the earth, and osculating the surface of the latter, the excentricity of this spheroid varies both with the latitude and the longitude of the place.

If the materials which compose the solid mass of the earth had equal capacities for heat and became liquid at equal temperatures, the spheroid of revolution would most probably be the figure assumed at the epoch when the cooling of the whole had rendered it solid. Such however is not the case; a great portion of the surface of the globe is yet liquid, and of the solid parts some must have assumed that state prior to others. It is also possible that the temperature of space is variable within the extent of the solar system, and therefore the conditions for the cooling of the northern and southern hemispheres may be different, and a very small difference would suffice to produce, in a long series of ages, a marked difference between the temperatures of the two hemispheres, and therefore a corresponding difference would arise relative to their forms. The general sphericity of the earth cannot be otherwise conceived than by its primitive fluidity, and the irregular cooling of its parts accounts sufficiently for the observed departures from the spheroidical shape, which would have been otherwise produced by the attraction of its parts and the centrifugal force of rotation. The other bodies of the solar system which have short periods of rotation present the analogous appearance of unequal axes, the equatorial axis being always the longer.

In the trigonometrical survey of portions of the earth's surface, the extent or area may be computed more and more approximately by the suppositions of such portions being plane, spherical, spheroidical, and lastly of being coincident with the osculating spheroid.

As the method of conducting ordinary surveys for topographical purposes will be explained under another head [SURVEYING], we shall here treat of geodetical measurements in reference only to general geography and the figure of the earth. We propose therefore to give a short historical notice of the principal trigonometrical surveys which have been undertaken in different parts of the world for measuring terrestrial degrees, or accurately delineating considerable portions of the earth's surface; to describe the general nature and objects of the operations to be performed in carrying on such surveys, and the principles upon which the computations are made; and to state the dimensions of the earth, considered as the spheroid of revolution, which have been deduced from the comparison of those measures of meridional arcs which appear to have been executed with the greatest precision.

The merit of first applying trigonometry to geodetic operations belongs to Willebrord Snell [SNELL, in BIOG. DIV.], who in 1617 undertook a survey of Holland, for the double purpose of establishing the geographical positions of the principal cities in that country, and measuring a degree of the terrestrial meridian. The method which he followed was the same in principle as that which would be adopted at the present time. Having formed a series of triangles extending over the country, he observed their angles with a quadrant, and computed their sides from a base which was carefully measured with wooden perches on the ground. He also determined the direction of the meridian at Leyden, and observed its inclination to a side of one of his triangles, and thereby obtained the bearings of the different angular points. Lastly, by observing the altitude of the pole-star with a five-feet quadrant at Alkmaar, Leyden, and Bergen-op-zoom, he determined the amplitudes of two celestial arcs; and on comparing the amplitudes with the terrestrial distances computed from the triangles, and reduced to the direction of the meridian, he concluded the length of a degree to be 28,500 Rheinland perches, or 55,100 French toises, equivalent to about 66¾ English miles. The result is about three miles too small. In 1621 Snell measured a new base, and was preparing to correct some errors which he had detected in the calculations, when his labours were cut short by his early death. Musschenbroek, a century afterwards, re-observed the latitudes, and revised the calculations, and found 1° = 57,003 toises, or 69 miles. (Snellius, 'Eratosthenes Batavus de Terræ ambitus vera quantitate,' &c., Lugduni Bat., 1617; Musschenbroek, 'Dissertationes Physicæ,' &c., Ib., 1729.)

About the middle of the same century Riccioli and Grimaldi undertook to measure an arc of a great circle of the earth in Lombardy. They formed a chain of triangles between Bologna and Modena, observed their angles with a quadrant, and computed their sides from a base measured on the road leading out of Bologna. The distance between the two cities was found to be 20,439 paces. Instead of reducing this distance to the meridian, according to the method of Snell, Riccioli sought to determine the arc of the vertical circle in the heavens intercepted between the zeniths of the two stations. This determination, which presumes an accurate knowledge of the latitudes and the declinations of the stars, could not, in the state of astronomy at that time, be made with sufficient precision, and accordingly the result was still more erroneous than that of Snell. He found the amplitude of the celestial arc to be 19′ 25″, whence 1° = 63,159 paces of Bologna, or nearly 74½ English miles. (Riccioli, 'Geographiæ et Hydrographiæ Reformatæ Libri XII.,' &c., Bononiæ, 1661.)

Picard, in 1669, undertook to measure the meridional arc between Paris and Amiens. This operation was conducted with far greater precision than any previous one of the same kind, and the result had a memorable application, as it furnished Newton with a sufficiently accurate knowledge of the earth's diameter, and consequently of the dimensions of the lunar orbit, to enable him to compute the force of terrestrial attraction at the distance of the moon, and thereby establish the law of gravitation. The angles were measured with a quadrant, furnished with telescopes having cross-wires in their foci (an improvement in the art of observing then newly introduced), and the sides computed from a base of 5663 toises. The latitudes were observed with a zenith sector at Malvoisine (near Paris), at Amiens, and at an intermediate point, so that two comparisons of celestial and terrestrial arcs were obtained, the mean of which gave 1° = 57,060 toises, equivalent to 364,876 English feet, or about 69·1 miles. This is a very near approximation to the true length of the degree at the same place, as it is given by recent and more exact determinations, but it proceeded, in part, from an accidental compensation of errors. (Picard, 'Mesure de la Terre,' folio, 1671; 'Dégré du Méridien entre Paris et Amiens, par M. Picard, avec les Observations de MM. de Maupertuis, Clairaut, Camus, Le Monnier, 8vo.' 1740.)

Picard's measurement gave rise to a more extensive operation,—the prolongation of the meridian through the whole extent of the French territory, and the construction of a geometrical map of France. The triangulation for this purpose was begun in 1683 by Dominic Cassini, but after a few angles had been measured, the work was suspended till 1700, when it was resumed, and in the following year the triangles were extended to the Pyrenees. The northern part, from Paris to Dunkirk, was completed by James Cassini, in 1718. Cassini adopted Picard's base, but two bases of verification were measured near the extremities of the arc. A very unexpected result was deduced from this operation. On comparing the celestial arc with the measured distance between the parallels of Paris and Collioure (the southern extremity), the length of the degree was found to be 57,097 toises, while the arc between Paris and Dunkirk gave 1° = 56,956 toises. From this it appeared that the degrees of the meridian become shorter as the latitude increases—a consequence directly opposed to the theory of attraction. (Cassini, 'Traité de la Grandeur et de la Figure de la Terre,' Paris, 1720; Amsterdam, 1723.)

The discussions to which this result gave rise in the Academy of Sciences were the immediate cause of the two celebrated expeditions to Peru and Lapland, which a few years later were undertaken under the auspices of the French government for the purpose of definitively settling the question of the compression of the earth. In 1735 Bouguer, La Condamine, and Godin, members of the Academy, set sail for Peru, where they were joined by two Spanish officers, Juan and Ulloa. From the unfavourable nature of the country, the defective state of their instruments, and other causes, this party encountered very great difficulties, and several years elapsed before they were enabled to complete their object. An arc was at length measured on the plain of Quito, between the parallels of 2′ 31″ N. and 3° 4′ 32″ S. lat. A primary base of 6274 toises was measured by Bouguer and Godin separately; and a base of verification at the southern extremity of 5259 toises was found to differ less than a toise from the length computed from the first base through the series of triangles. The measuring-rods were of deal, 20 feet in length, and compared daily with an iron toise, which from this application has been called the toise of Peru, and become celebrated in the history of geodesy, being in fact the standard to which all the degrees measured on the Continent have been ultimately referred, and in terms of which the greater number of them have been expressed. The angles were measured with quadrants of 2½ feet radius, and reduced to the horizon by calculation; in some instances the difference of altitude of two signals observed from the same station exceeded a mile. The latitudes at the extremities were observed simultaneously with zenith sectors. Three different results were computed. Bouguer found the length of the degree, reduced to the sea-level, to be 56,753 toises at the temperature of 13° of Réaumur's scale (61¼° Fahrenheit); Condamine found 56,749 toises, and the Spanish officers 56,768 toises. (Bouguer, 'La Figure de la Terre,' &c., 1749; Condamine, 'Mesure des Trois Premiers Dégrés de Méridien dans l'Hemisphère Australe,' 1751; Juan and Ulloa, 'Voyage Historique de l'Amérique méridionale,' 1752.)

While Bouguer and his associates were carrying on their operations in Peru, an arc of the meridian was measured near the polar circle by Maupertuis, Clairaut, Camus, Lemonnier, and Outhier. This party reached Tornea, at the extremity of the Gulf of Bothnia, in 1736, and established a chain of triangles along the line of the river stretching northward to the parallel of 66° 48′ 22″ N. lat. A base was measured on the frozen surface of the river. The latitudes were observed with a zenith sector by Graham. The amplitude was found to be 57′ 29″·6, and the terrestrial distance between the parallels 55,023 toises; whence 1° = 57,422 toises, exceeding Picard's degree by 362 toises. This result (which however is now supposed to err considerably in excess) put an end to all doubts respecting the decrease of the meridional degrees on going from the equator, and the consequent compression of the earth at the poles. (Maupertuis, 'La Figure de la Terre déterminée par les Observations au Cercle Polaire,' 1738.)

Soon after the return of Maupertuis and his party from the polar circle, an important survey was undertaken in France by Cassini de Thury and Lacaille, for the purpose of verifying the former measure of the meridian and laying the foundation of an accurate map of the kingdom. Six new bases were measured, each twice; that near Paris five times. The angles were observed with a 2-feet quadrant, and were reduced to the horizon and centre of the station. The latitudes were observed at the extremities and three intermediate stations; and the length of the degree deduced from each of the four arcs. The results are not now important, as the same arc has since been measured with still greater precision by Mechain and Delambre. In the course of the operation the length of a degree of longitude was also determined. The terrestrial arc extended across the mouth of the Rhône from Cette in Languedoc to Mont St. Victoire in Provence; and the difference of longitude was found by exploding gunpowder in the open air at an intermediate station, and noting the difference of the apparent times at which the flash was seen at both extremities. ('La Méridienne de l'Observatoire Royal de Paris Vérifiée, &c.,' 1744.)

In 1751 Boscovich and Lemaire began a survey of the Papal States, and in the course of the operation determined the meridional distance between the parallels of Rome and Rimini. The sides of the triangles were computed from a base measured on the seashore near the latter place, which consisted of two parts making an angle of 170° 52′ 15″. Another base was measured on the Via Appia, near Rome. The angles were observed with a quadrant of 3 feet, and the latitudes with a sector of 9 feet. The result gave 1° = 56,979 toises; but it has been shown to be affected with errors of considerable magnitude. (Boscovich, 'De Litteraria Expeditione per Pontificam Ditionem ad dimentiendos duos Meridiani Gradus, &c.,' Romæ, 1755; De Zach, 'Correspondance Astronomique,' vol. vi.)

Lacaille, in 1752, measured an arc of meridian at the Cape of Good Hope. The two extremities were connected by two large triangles, whose common side was deduced by means of two small triangles from a base of 6467·25 toises (7·8 miles), situated near the middle of the arc. The amplitude (1° 13′ 17″·33) was determined with a zenith sector of 6 feet, and the angles were measured with a 3-feet quadrant. The final result gave 1° = 57,037 toises, or 364,728 English feet, which is nearly equal to the degrees measured in France, 10° farther from the equator. (Lacaille, 'Mémoires de l'Acad. Royale des Sciences' for 1751; 'Fundamenta Astronomiæ,' 1759.) It will be seen that Mr. Maclear has recently succeeded in satisfactorily accounting for this apparent anomaly.

Beccaria, between 1762 and 1764, measured an arc of the meridian in Lombardy. The instruments and methods used were similar to those of Boscovich. The amplitude was 1° 7′ 47″·7, and the length of the degree found equal to 57,468 toises. This result greatly exceeds that which other measurers gave reason to expect; and the cause has been ascribed to the disturbance of the plumb-line of the sector by the attraction of the mountain masses on which the arc abutted at both extremities. (Beccaria, 'Gradus Taurinensis,' &c., 1774.) This arc was re-measured by Plana and Carlini in 1822, who found the amplitude to be 1° 7′ 31″·07, and the degree equal to 57,625 toises, a result still more at variance with other determinations.

Two surveys, executed by Liesganig in Austria and Hungary, between 1762 and 1769, have been usually cited in the history of geodetic measures, but are now known to be deserving of no credit. The Austrian operation comprehended nearly three degrees of the meridian of Vienna, from Brunn in Moravia, to Varasdin in Croatia; and since the beginning of the present century the triangles have been re-measured in the course of a general trigonometrical survey of the Austrian states. For some distance from Brunn, Liesganig's results agree with the recent ones; but in the last triangles (in consequence, it is supposed, of mistaking a signal) the errors in the length of the sides are from 1066 to 2509 toises; while that in the length of the meridional arc amounts to 4533 toises. Baron Zach, who examined the manuscripts of Liesganig, affirms that both the astronomical and geodetical observations were not only faulty and ill calculated, but designedly altered to produce a better agreement. (Liesganig, 'Dimensio graduum Meridianii Viennensis et Hungarici,' Viennæ, 1770; De Zach, 'Correspondance Astronomique,' vol. vii.)

The resolution adopted by the French Convention in 1791 to establish a decimal system of weights and measures of which the unit should be an aliquot part of the quadrant of the meridian, gave rise to a remeasurement of the meridian of Paris from Dunkirk to Barcelona. In the conduct of this survey, the most important in reference to the figure of the earth that has yet been executed, the French astronomers introduced numerous important improvements both into the theory and practice of geodesy. The northern part, from Dunkirk to Rhodez, including about two-thirds of the whole, was assigned to Delambre, and the southern, from Rhodez to Barcelona, to Mechain. Two bases were measured near the extremities; one at Melun, the other near Perpignan, by a method which will be described farther on. All the angles, geodetical and astronomical, were measured with repeating circles, and the observations were examined and compared by special commissioners, who fixed the mean values to be used, and directed the calculations. The azimuths and latitudes were determined at five stations, Dunkirk, Paris, Evaux, Carcassonne, and Montjouy, so that the whole was divided into four partial arcs, the lengths and amplitudes of which are given in the table at the end of this article. No doubt can be entertained of the excellence of the geodetical part of this celebrated operation, but the latitudes have been considered liable to some uncertainty, owing to the feeble power of the telescope and other causes depending on the nature of the instruments with which the observations were made. [REPEATING CIRCLE.] In fact, when Mechain had occasion to determine the latitude at Barcelona, which is only about a mile distant from Montjouy, he found a discordance between the results at these two places amounting to 3″, and all his efforts to reconcile or explain the inconsistency were fruitless.

From the results of this operation, compared with the degree measured in Peru, the dimensions and ellipticity of the earth were deduced, and the *mètre* determined. The earth was assumed to be a spheroid of revolution; the deduced ellipticity was 1÷334; and the *mètre*, or ten-millionth part of the quadrant of the meridian, at the temperature of freezing water, was fixed at 443,296 lines of the toise of Peru, the normal temperature of the iron toise being 13° of Réaumur, or 61° 15′ of Fahr. ('Base du Système Métrique Décimale;' 3 vols. 4to., Paris, 1805, 1807, 1810.)

The prolongation of the meridian through Spain, which formed a part of the original project, was interrupted by the death of Mechain, but was subsequently effected (1807-1809) by Biot and Arago. By means of a very large triangle, one side of which exceeded 100 miles, they connected the island of Iviza with the coast of Valentia; and another triangle carried the arc to Formentera, a small island still farther to the south. The amplitude was thus increased to upwards of 12⅓ degrees. (Biot and Arago, 'Recueil d'Observations Géodesiques,' &c., 1821.)

It is a circumstance deserving of notice, that notwithstanding the parade of a commission and the extraordinary precautions taken to ensure accuracy in the computations, a serious error was committed with respect to this arc, which was only recently detected by Puissant. It appears that, through inadvertence or the misapprehension of a formula, the distance between the parallels of Montjouy and Mola (the station on Formentera) was computed without applying the proper correction for the convergence of meridians. The distance originally given by the commissioners was 153605·77 toises; but the distance when the computation is correctly made is 153673·61 toises (Bessel, 'Astronomische Nachrichten,' No. 438), the difference being 67·84 toises. In consequence of this correction, and of the introduction of some other arcs since measured into the data for determining the figure of the earth, the length of the quadrant of the meridian expressed in terms of the legal *mètre*, according to the best determination which can at present be made of the dimensions of the earth, is 10,000,855·76 *mètres*; in other words, the legal *mètre* would require to be lengthened by about the ·00,000,856th part of itself in order to agree with the ideal *mètre*, a ten-millionth part of the quadrant of the elliptic meridian. This circumstance may serve to show the futility of any proposal to restore a lost standard from its assigned relation to the magnitude of the earth. The French *mètre* is in fact nothing more than an arbitrary part of the toise of Peru, in terms of which the bases were measured and the meridian computed.

The arc which was measured by Maupertuis and his associates in Lapland in 1736, was remeasured by Svanberg in 1801-1803, and extended in both directions so as to increase the amplitude about 40″. A new base was measured with iron bars which were compared with a standard *mètre* in Paris. The terrestrial angles, as well as the latitudes and azimuths, were measured with repeating circles, and the methods of observing and computing the results the same generally as those of Delambre. All the details of the operation appear to have been executed with great skill and ability: but by reason of the inadequateness of the instrument, the latitudes are not supposed to be very certainly determined; and there is some doubt with respect to the temperature at which the measuring-rods were compared with the standard *mètre*. The result gave 1° = 57,196 toises, which agrees much better than that of Maupertuis with other determinations. (Svanberg, 'Exposition des Opérations faites en Lapponie pour la Détermination d'un Arc du Méridien,' &c., Stockholm, 1805.)

A trigonometrical survey of Holland was executed under the direction of General Krayenhoff, from 1801 to 1809, which may be regarded as a continuation of the general survey of France. No base was measured, but the distances were computed from a side of one of Delambre's adjacent triangles. The angles were measured with repeating circles, and Delambre's methods adopted throughout. As a verification, some distances were deduced from two different series of triangles, and the greatest discordances were found to amount only to one *mètre* in 9128. ('Précis Historique des Opérations Géodésiques et Astronomiques faites en Hollande pour servir de base à la Topographie de cet état; Exécutées par le Lieutenant-Général Krayenhoff,' &c., À la Haye, 1815.)

The first geodetic survey executed in England was undertaken with the immediate object of establishing a trigonometrical connection between the observatories of Paris and Greenwich, in order to determine the difference of longitude. A memoir on the subject, drawn up by Cassini de Thury, was in 1783 presented by the French ambassador to the king, who placed funds at the disposal of the Royal Society for providing the requisite apparatus. In order to accomplish the proposed object, it was necessary to connect the observatory of Greenwich with the French arc of meridian, by carrying a series of triangles from

Greenwich to Dunkirk. This was undertaken by General Roy, who began his operations by measuring a base of 27,404 feet on Hounslow Heath in the summer of 1784. For the measurement of the angles a large and exquisitely divided theodolite, having a horizontal circle of three feet in diameter, and carrying telescopes of 36 inches focal length —an instrument far superior to any that had ever been employed in geodetical observations—was constructed by Ramsden. In the summer of 1787, the triangulation was begun by General Roy, assisted by Mr. Dalby, and before the end of the year it was carried to the eastern coast of Kent, and connected with a series of triangles on the opposite coast, which had been extended from Dunkirk to Calais and Boulogne, by Cassini, Méchain, and Legendre. Throughout the whole of this survey the practical operations were conducted with a degree of accuracy and precision, of which, till that time, there had been no example. The methods of calculations were however less excellent; the sum of the three observed angles of each triangle was made equal to 180° by an arbitrary correction, and the sides computed by plane trigonometry. By reason of the small extent of country surveyed, the neglect of the earth's curvature did not lead to any serious error, but such a method of proceeding would be inadmissible at the present day. A base of verification of 28,535 feet was measured on Romney Marsh with a steel chain, and the difference between the measured length and the length computed from the Hounslow Heath base through the series of triangles was found to be only about 28 inches. So near an agreement might afford a satisfactory proof of the general accuracy of the work, but this has since been submitted to a more decisive test. In 1821 and some of the following years, the angles were remeasured by Colonel Colby and Captain Kater, with the same excellent instrument, and the triangles calculated with reference to the sphericity of the earth. On comparing the results with those of General Roy, the greatest difference was found to be in the distance between the signals at Dover and Calais, and this amounted only to 12½ feet, the whole distance being 137,472 feet. (Roy, 'Phil. Trans.' 1790; 'Trigonometrical Survey of England and Wales,' vol. 1; Kater, 'Phil. Trans.,' 1828.)

The operations for establishing a geodetic connection between the observatories of Greenwich and Paris had the effect of suggesting the expediency of a general survey of the British isles. This great national undertaking was commenced in the year 1791. The operations were conducted by Colonel Williams, and Captain (afterwards General) Mudge, of the Royal Engineers, and Mr. Dalby, who had previously assisted General Roy. Their first step was to remeasure the base on Hounslow Heath. This was effected by means of two steel chains, each 100 feet long, which had been carefully constructed for the purpose by Ramsden. The length of the base was found to be 27404·24 feet, a result differing only 2¼ inches from that obtained by General Roy. [ROY, MAJOR-GENERAL, in BIOG. DIV.] The terrestrial angles of the survey were measured with two large theodolites by Ramsden, each 3 feet in diameter; and a smaller theodolite, by the same artist, of 18 inches diameter. In 1801, it reached Clifton in Yorkshire. The length of the arc of the meridian extending from Dunnose in the Isle of Wight to this station was determined in the following year by General Mudge. In 1806 the arc was prolonged to Burleigh Moor, about a degree to the north of Clifton. At the same time the triangulation had extended considerably over other parts of England. In the course of these operations three bases of verification were measured; one on Salisbury Plain (1794), by Lieutenant-Colonel Williams and General Mudge [MUDGE, GENERAL, in BIOG. DIV.]; one on Misterton Carr, near Clifton (1801), by General Mudge; and one on Rhuddlan Marsh, in Wales (1806), by the same officer. These various bases were measured with the same steel chains which were employed in the measurement of the base on Hounslow Heath. The astronomical latitudes of six stations on the arc of the meridian extending from Dunnose to Burleigh Moor, namely, Dunnose, Greenwich, Clifton Beacon, Arbury Hill, Delamere, and Burleigh Moor, were determined with a zenith sector of 8 feet radius, constructed by Ramsden. The operations of the survey down to 1811 are recorded in a work, the concluding volume of which was published in the year just mentioned. ('An Account of the Operations carried on for accomplishing a Trigonometrical Survey of England and Wales, &c.; by order of the Honourable Board of Ordnance,' by Captain Mudge, R.A., Mr. Dalby, and Captain Colby, R.E.; 3 vols., 1799-1811.)

The triangulation continued without interruption to be extended towards the north. In 1817, a new base of verification was measured on Belhelvie Links, near Aberdeen, by Major-General Colby, with the assistance of Mr. Gardner. The same instruments of measurement were employed on this as on previous occasions of a similar kind. In 1820, upon the death of General Mudge, General (then Captain) Colby was appointed Superintendent of the Ordnance Survey. In 1824, the operations for the survey of Ireland were commenced. A base was shortly afterwards (1827-8) measured on the shores of Lough Foyle, in the county of Londonderry. ('An Account of the Measurement of the Lough Foyle Base, in Ireland, &c.,' by Captain William Yolland, R.E., 1847.) The apparatus of measurement differed on this occasion from that employed in ascertaining the lengths of the previous bases, consisting of a combination of bars of different metals, so adjusted as, by their unequal expansion, to obviate the varying effects of temperature. A description of this apparatus, which was devised by Colby, will be given presently. The triangulation was rapidly extended over Ireland. The instruments were the same as those which had been used in the survey of England, with the addition of a 2-foot theodolite constructed by Troughton & Simms. The triangulation was connected at several points with the triangles observed in England, Wales, and Scotland. The astronomical latitudes continued to be determined with Ramsden's zenith sector until 1841, when it unfortunately was destroyed in the course of the conflagration which burned a considerable portion of the Tower of London in that year. An account of the operations with this fine instrument was published in the following year. ('Astronomical Observations with Ramsden's Zenith Sector,' 1842.) The subsequent determinations of latitude were effected with a new zenith sector, devised by Mr. Airy, the astronomer-royal, with the view of obviating certain inconveniences which attended the use of Ramsden's instrument. Three important principles of a novel character were involved in the construction of Airy's zenith sector. "The first principle was the arrangement for making successive observations in two positions of the instrument, face east and face west, at the same transit. The second was the substitution of a level, or system of levels, for the usual plumb-line. The third principle was the casting in one piece, as far as practicable, of each of the different parts of the instrument, in order to avoid the great number of screws and fastenings with which most instruments are hampered, and to secure, if possible, perfect rigidity." An account of the observations with this sector was published in 1852. ('Astronomical Observations with Airy's Zenith Sector, from 1842 to 1850,' by Captain William Yolland, R.E.)

At the stations of Balta in Shetland, Cowhythe in Aberdeenshire, and Dunnose in the Isle of Wight, the latitudes were determined first with Ramsden's and subsequently with Airy's zenith sector. A comparison of the results affords satisfactory evidence of the degree of precision attained in such observations. Thus we have—

Station.	Airy.	Ramsden.	Difference.
Dunnose . . .	50°37′6″·98	50°37′7″·09	0″·11
Balta	60 45 1 ·68	60 45 2 ·31	0 ·63
Cowhythe . .	57 41 9 ·58	57 41 9 ·74	0 ·16

In 1849 the base on Salisbury Plain was re-measured with Colby's compensation bars. The result, in combination with the Lough Foyle base, has formed the groundwork of all the subsequent computations connected with the triangulation, the other bases having been used merely for purposes of verification.

Upon the retirement of General Colby in 1847, Colonel Hall was appointed Superintendent of the Ordnance Survey. In 1858 a work was published by Colonel James, who has recently succeeded Colonel Hall as superintendent of the survey, containing a complete account of the observations and calculations relative to the triangulation of the British Isles, with an investigation of the figure, dimensions, and mean density of the earth, as deducible from the results in combination with the data of the same kind which had hitherto been established. ('Ordnance Trigonometrical Survey of Great Britain and Ireland;' 'Account of the Observations and Calculations of the Principal Triangulation, and of the Figure, Dimensions, and Mean Specific Gravity of the Earth, as derived therefrom,' drawn up by Captain Alexander Ross Clarke, R.E., &c., under the direction of Lieut.-Colonel H. James, R.E., &c., Superintendent of the Ordnance Survey, 4to, London, 1858.) The triangulation embraces an arc of the meridian extending from Dunnose in the Isle of Wight to Saxavord, the most northerly of the Shetland Isles. The former of these stations is situate in lat. 50° 37′ 3″·748; the latter in lat. 60° 49′ 41″·992. The amplitude of the arc is, consequently, 10° 12′ 38″·244.

It has been stated that the terrestrial distances were computed from the base lines measured on Salisbury Plain (1849), and on the shore of Lough Foyle, in Ireland. The difference between the measured length of each of these bases and the length computed from the other base was found to amount to 0·4178 feet, or about 5 inches. From this result a mean base has been derived by the theory of probabilities, and this mean base has been used as the immediate groundwork of all the subsequent calculations. The following table exhibits a comparison between the lengths of the bases as measured and reduced to a common standard, and their lengths as determined by the triangulation :—

Date.	Base.	Length in terms of Ordnance Standard O_1*	Length in Triangulation	Difference.
		Feet.	Feet.	Feet.
1791	Hounslow Heath .	27406·190	27406·363	+ 0·173
1794	Salisbury Plain .	36576·830	36577·656	+ 0·826
1801	Misterton Carr . .	26344·060	26343·869	— 0·191
1806	Rhuddlan Marsh .	24516·000	24517·596	+ 1·596
1817	Belhelvie . .	26517·530	26517·770	+ 0·240
1827	Lough Foyle . .	41640·887	41641·103	+ 0·216
1849	Salisbury Plain .	36577·858	36577·656	— 0·202

Many of the sides of the triangles are of great length, especially those which connect the triangulation of Ireland with the stations on the opposite coasts of England, Wales, and Scotland. The following is a statement of the sides which exceed 90 miles; the names given are those of the stations at the extremities of each side. The letters appended to each station serve to indicate whether the station is situate in England (E.), Wales (W.), Scotland (S.), Ireland (I.), or Isle of Man (I. M.):—

The length of the entire arc of the meridian included between Dunnose and Saxavord was found to be 3,729,334·07 feet. The distances between the parallels of Dunnose, Arbury, Clifton, Easington, and Saxavord were separately computed. The following are the results:—

	Feet.
Dunnose to Arbury	586,356·36
Arbury to Clifton	450,225·16
Clifton to Easington	404,325·22
Easington to Saxavord	2,288,427·33
	3,729,334·07

The distance between the parallels of Easington and Saxavord, which lie very nearly upon the same meridian, was computed by two different systems of triangles. The results were:—

2,288,427·29 feet, by the one system of triangles.
2,288,427·38 feet, by the other „

Mean 2,288,427·33.

By the first calculation, the distance of Saxavord from the assumed meridian at Easington was 222·56 feet; by the second calculation it was 221·94 feet. The difference of the two results amounts to only 0·62 feet.

The operations connected with the great Trigonometrical Survey of India have resulted in the measurement of an arc of the meridian which in extent is second only to the Russo-Scandinavian Arc, to be presently alluded to. This important undertaking was commenced in the year 1801, under the superintendence of Colonel Lambton. A base was measured in the neighbourhood of Madras, which served as the groundwork for the measurement of an arc of the meridian of about a degree and a half in amplitude. By a course of triangulation, Colonel Lambton subsequently advanced westward to a place called Dodagoontah, about 170 miles distant from Madras, where he measured a second base. He now directed his operations southwards, forming a chain of triangles which ultimately reached Punnæ (Lat. 8° 9′ 35″) near Cape Comorin. Bases of verification were measured both at the middle of the arc and at the southern extremity. The arc was subsequently prolonged northwards by Colonel Lambton as far as Damargida, in lat. 18° 3′ 15″. Near this station, at Beder, another base of verification was measured in the year 1815.

The amplitude of the Indian arc, extending from Punnæ to Damargida, it will be seen, now amounted to 9° 53′ 40″. With the view of prolonging it still further north, Colonel Lambton measured a base near Takal Khera, which he intended to be the limit of the next section of the arc. Upon the death of that officer in 1823, Colonel (then Captain) Everest was appointed his successor, by whom the triangulation was continued from Damargida to Kalianpur, in lat. 24° 7′ 11·8″ near which, in the plain of Seronj, another base of verification was measured.

The base lines determined by Colonel Lambton and Colonel Everest in the course of the operations to which allusion has just been made, were measured with a steel chain a hundred feet long, as in the case of the earlier measurements of a similar kind connected with the survey of the British Isles. The terrestrial angles were measured with a theodolite, 3 feet in diameter, constructed by Cary, and the latitudes were ascertained with a zenith-sector of 5 feet radius, by Ramsden. It would appear, according to the candid exposition of Colonel Everest, that the results of Colonel Lambton's operations, and of those hitherto conducted by himself, are not entitled to so high a degree of reliance as the present advanced state of geodesy demands. The azimuthal circle of the great theodolite had received an accidental blow, and although Colonel Lambton had, to a great extent, succeeded in obviating the effects of the injury, still the subsequent use of the instrument, even with the utmost precaution, could not be regarded as altogether unexceptionable. Again, it was found that previous to the measurement of the base at Takal Khera, the joints of the chain were found to be thickly covered with rust, the removal of which could scarcely have failed to affect the length of the chain. In the measurement of the base, the chain was not supported on coffers, or stretched by a constant weight. The process employed was to lay it on the ground and stretch it by means of a hand-capstan. The length of the Beder base when computed through the series of triangles from the base at Takalkhera was found to differ from its measured length by 78·72 inches. It was clear therefore that the results did not possess all the precision desirable in such important operations. Great allowance must, however, be made for the difficulties arising from the climate and other unfavourable circumstances. (Lambton, 'Asiatic Researches,' vols. viii., x., xii., xiii.; 'Phil Trans,' 1818; Everest, 'Account of the Measurement of an Arc of the Meridian between the Parallels of 18° 3′, and 24° 7′, &c.', 1830.)

Colonel Everest, who had been compelled by ill-health to proceed to England, returned to India in 1830, with the view of resuming his geodetical labours. For this purpose the East India Company had provided him with an ample supply of instruments of the very first quality. He commenced his operations with the measurement of a base at Dhera Dun, near Kaliana, in lat. 29° 30′ 48″, about 70 miles from the foot of the Himalayas. On this occasion the measurement was effected with bars provided with Colby's compensation apparatus. From Kaliana the triangulation was extended southwards until at length in 1837 it reached Kalianpur, the northern extremity of the great arc. Upon computing the length of the Seronj base, which had been measured in 1824, from the recently measured base at Dhera Dun, it was found that the measured and computed results differed to the extent of 3½ feet. In consequence of this discordance, Colonel Everest measured the Seronj base anew. This important operation was brought to a close in the early part of 1838. It appeared from the result that an error of nearly 3 feet had been committed in the measurement of 1824.

In order to remove all suspicion from the measurement of the arc included between Damargida and Kalianpur, Colonel Everest, taking advantage of an interruption of his labours, occasioned by the necessity of modifying the instruments for determining the celestial amplitudes, resolved to determine afresh the whole terrestrial distance between those two stations. The triangulation was effected by Captain Waugh and Captain Renny. In 1840 a new base was measured by Captain Waugh in the vicinity of Damargida. It was found impossible to identify the site of the old Beder base measured by Colonel Lambton in 1815. The results of the new base measurements were found to be extremely satisfactory. The length of the Dhera Dun base, when computed from the Seronj base, was 39183·273 feet. The measured length was 39183·873 feet. The difference consequently amounted to only 0·600 feet, or rather more than 7 inches, while the distance between the two bases was about 480 miles. The result of a comparison of the measured length of the Beder base and its length as computed from the Seronj base was equally satisfactory. In this case, although the distance between the two bases amounted to 426 miles, the difference between the measured and computed results was only a little more than 4 inches.

For ascertaining the amplitudes of the two sectional arcs, Kaliana-Kalianpur, and Kalianpur-Damargida, Colonel Everest employed the method founded on simultaneous observations, at the extremities of each arc, of the zenith distances of certain stars selected beforehand for the purpose. The observations were made with two vertical circles, 3 feet in diameter. The amplitude of the northern section was determined by observations of thirty-six stars, one half to the north and the other half to the south of the zeniths of both stations. The observations at Kaliana, which were made by Colonel Everest and Captain Renny, were nearly, but not quite, simultaneous with those made at Kalianpur by Captain Waugh. For the determination of the amplitude of the southern section of the arc, extending from Kalianpur to Damargida, thirty-two stars were simultaneously observed. The results gave 5° 23′ 37″·051 for the amplitude of the arc between Kaliana and Kalianpur, and 6° 3′ 55″·973 for the amplitude of the arc between Kalianpur and Damargida. The amplitude of the entire arc measured by Colonel Everest consequently amounts to 11° 27′ 33″·024. If to this we add 9° 53′ 40″, the amplitude of the arc measured by Colonel Lambton, we obtain 21° 21′ 13″·024 for the entire length of the great meridional arc of India. ('Account of the Measurement of Two Sections of the Meridional Arc of India, Bounded by the Parallels of 18° 3′ 15″; 24° 7′ 11″; and 29° 30′ 48″.' By Lieutenant-Colonel Everest. London, 1847.)

The great meridional arc of Russia originated in the operations connected with the trigonometrical survey of the Russian empire.

In 1819, M. Struve, who was then director of the observatory of Dorpat, while engaged in the survey of Livonia, suggested to the university of Dorpat the desirableness of measuring the arc of the meridian included between the island of Hogland in the Gulf of Finland, and the town of Jacobstadt in the province of Courland. The sanction of the emperor having been obtained for the project, the operations were commenced, and were finally completed in the year 1827. The terrestrial angles were measured with Reichenbach's *Universal Instrument*. The latitudes of the stations were determined by observations with a transit adjusted in the prime vertical. The arc measured 3° 35′ 5″, and passed very nearly through the meridian of the observatory at Dorpat. In the same year in which M. Struve brought to a close the operations connected with this arc, General Tenner also completed the measurement of the arc of the meridian included between Bristen in Courland, and Belin in the province of Grodno. The amplitude of this arc was found to be 4° 32′. As Belin, the northern station of this arc, was distant only 4′ 47″ from Jacobstadt, the southern station of the Livonian arc, it became desirable to connect trigonometrically the two arcs together. This was effected in 1827–8, by M. Struve and General Tenner, independently of each other, and the results upon being transmitted separately in sealed letters to Bessel, were found to exhibit a most satisfactory accordance. The amplitude of the entire arc thus measured between Hogland and Belin amounted to 8° 2′ 28″. (Struve, 'Beschriebung der Breitengrad messung in den Ostseeprovinzen Russlands,' &c. Dorpat, 1831.)

In 1845, the Russian arc was extended northwards as far as Tornea, the southern extremity of the Lapland arc. It thereby received an accession of length amounting to 5° 26′. M. Struve had for his principal coadjutor on this occasion, M. Wolstedt, who was subsequently appointed director of the Observatory of Helsingfors. While the arc was being prolonged towards the north, General Tenner was engaged in extending it southwards, until it reached the northern frontier of the province of Bessarabia. By this operation its length received a further increase of 3° 17′ 47″. The entire arc now extended from Tornea in lat. 65° 50′ 34″ to Souprounkontsi in lat. 48° 45′ 1″. It consequently possessed an amplitude of 17° 5′ 33″. In 1849 it was extended southwards through the entire province of Bessarabia to Ismail on the Danube. The amplitude of the entire arc now amounted to 20° 31′.

Under the auspices of the Swedish government the Russian arc of the meridian has been extended to the Arctic Ocean. The Norwegian portion of the arc was executed by M. Hansteen, of Christiania, and the Swedish portion by M. Selander, Director of the Observatory of Stockholm. The Swedish arc extends from Tornea in lat. 65° 51′, to Atjick in lat. 68° 54′. Its amplitude therefore amounts to 3° 3′. The Norwegian arc extends from Atjick to Fuglenaes, in lat. 70° 40′, and consequently embraces an amplitude of 1° 46′. The two arcs together measure 4° 49′.

The Russo-Scandinavian arc of the meridian now extends from Ismail on the Danube, lat. 45° 20′ 20·8″, to Fuglenaes on the Arctic Ocean, lat. 70° 40′ 11″·3. Its amplitude amounts to 25° 20′ 8″·5; and it is consequently the largest arc of the meridian which has been hitherto measured on the earth's surface. (Struve, 'Exposé historique des travaux executés jusqu'à la fin de l'année 1851, pour la mesure de l'arc du Méridien entre Fuglenaes, 70° 40′, et Ismail, 45° 20′, &c.;' St. Petersbourg, 1852.)

Two arcs of meridian have been measured in Hanover and Denmark, which, though of comparatively small extent, are very valuable by reason of the skilful manner in which the operations were conducted, and the great probable accuracy of the results. The first was obtained by connecting the two observatories of Göttingen and Altona, which are situated nearly in the same meridian, by means of a chain of triangles proceeding from a base which was measured by Gauss in 1820. From the same base another chain of triangles was carried through Denmark, by means of which the geodetical distance between the parallels of Lauenburg (in Hanover) and Lysabbel (in the island of Alsen) was computed. The celestial arc was determined by Schumacher with Bradley's zenith sector, sent from the observatory at Greenwich for the purpose. (Gauss, 'Bestimmung des Breitensunterschiedes swischen den Sternwarten von Göttingen und Altona, &c.'; Bessel, 'Astron. Nachrichten,' No. 333.)

An arc, of which the amplitude is 1° 30′ 28″, was also measured in Prussia, by Bessel, between 1831 and 1838. The immediate object of this undertaking was to connect the Russian triangulation with a chain of triangles which had been measured in the western part of Prussia, extending through Hesse, Thuringia, and Brandenburg, to Silesia, and connecting the Dutch (and thereby also the French and English) triangles with those of Bavaria and Austria. In this operation Bessel included the measure of an arc of the meridian of Königsberg. A base of 935 toises was measured with great precision. The angles were observed with a theodolite of 15 inches diameter, and the latitudes at the two extremities (Truntz and Memel) determined, as in Struve's method, with a transit-instrument adjusted in the prime vertical. The details are given by Bessel in a work which should be in the hands of every one concerned with geodetical operations of the highest order. (Bessel, 'Gradmessung in Ost-Preussen und ihre Verbindung mit Preussischen und Russischen Dreieckskotten, Berlin,' 1838.)

The anomalous nature of the result deduced by Lacaille, from his measurement of an arc of the meridian at the Cape of Good Hope, has been already alluded to. It is gratifying to learn that Mr. Maclear, by remeasuring and extending Lacaille's arc, has succeeded in completely removing the difficulty arising from this cause, and has obtained results which exhibit a most satisfactory accordance with the theory of gravitation. It is understood that the details of Mr. Maclear's labours will shortly be published. The amplitude of the arc measured by him amounts to 4° 11′ 45′ ·538. The following table exhibits a comparison between the observed latitudes at the various stations of the arc, and the corresponding latitudes calculated from Airy's elements of the earth's figure.

Station.	Observed Lat.	Cal. Lat.	Diff.
North End of arc	29°44′17″·66	29°44′17″·35	+ 0″·31
Kamies Sector Berg	30 21 29 ·10	30 21 20 ·73	+ 8 ·37
Heerenlogements Berg	31 58 9 ·11	31 58 9 ·64	— 0 ·53
Royal Observatory	33 56 3 ·20	33 56 3 ·20	. . . .
Zwart Kop	34 13 32 ·13	34 13 33 ·80	— 1 ·67
Cape Point	34 21 6 ·26	34 21 6 ·80	— 0 ·54

Mr. Maclear remarks that the disturbing effect produced by the attraction of the immense Bushman Table Land, the mean elevation of which above the level of the sea exceeds 3000 feet, is sufficient to account for the deflection observed at Kamies Berg.

We shall conclude this historical sketch of geodetical operations with a brief statement of the results deduced by Mr. Airy from the measurement of the arc of longitude comprised between the Royal Observatory, Greenwich, and Feaghmain, a station of the Ordnance Survey, situate in the island of Valentia, on the west coast of Ireland. The plan proposed by Mr. Airy, was to ascertain the difference of longitude of the two stations by the triangulations of the Ordnance Survey, assuming the elements of the earth's figure as previously determined by him, and to compare the result with the difference of longitude derived from the transportation of chronometers. The operations connected with this object were carried into effect in the year 1844. The following are the final results, the intermediate stations of Liverpool and Kingston (Dublin), through which the chronometers passed, being also included in the investigation.

	m.	s.
Geodetic arc of longitude from Greenwich to Liverpool	12	0·35
Chronometric arc	12	0·05
Chronometric arc smaller		0·30
Geodetic arc from Greenwich to Kingston	24	31·48
Chronometric arc	24	31·20
Chronometric arc smaller		0·28
Geodetic arc from Greenwich to Feaghmain	41	23·07
Chronometric arc	41	23·23
Chronometric arc larger		0·16
Geodetic arc from Liverpool to Kingston	12	31·13
Chronometric arc	12	31·15
Chronometric arc larger		0·02
Geodetic arc from Kingston to Feaghmain	16	51·59
Chronometric arc	16	52·03
Chronometric arc larger		0·44

By means of the different surveys to which we have now alluded the greater part of Europe has been covered with chains of triangles, whereby not only the geographical positions of all the principal places and remarkable objects have been determined by actual measurement, but all the measured arcs of meridian and parallel, and all the principal observatories have been trigonometrically connected with each other. The comparison of the astronomical and geodetical positions of so many connected points is, perhaps, even better calculated to lead to an accurate knowledge of the local configuration of this quarter of the globe than the measurement of isolated degrees.

We proceed now to give a general view of the methods of conducting a trigonometrical survey, and computing the results of the observations.

Measurement of the Base.—The foundation of every trigonometrical survey is the measurement of a ground-line, or base, in terms of which all the distances are to be computed. This is an operation which is attended with considerable difficulty, and requires to be executed with the most minute precision; for any error with which the result may be affected is multiplied in the sides of the triangles in the ratio of their length to the length of the base; and all other distances concluded from the survey are affected in the same proportion. An error in the base amounting only to an inch in the mile would vitiate the determination of the earth's diameter to the extent of 110 yards.

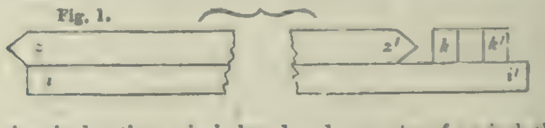
The general method of proceeding may be thus described:—A piece of ground must be selected as free from obstructions and as nearly level as possible. The terminal points must be defined by permanent marks; for example, by a fine dot, or the intersection of two straight lines, on a plate of metal, securely fixed in the ground. In order to trace the line of the base, a transit-instrument is adjusted over one of the terminal points, and directed to a flag-staff or other signal erected at the other, by which means the observer is enabled to direct an assistant to plant pickets in the ground, all ranging in the same vertical plane. The measuring apparatus may be constructed and applied in various ways, but in all cases the following conditions must be observed :—1, The successive measuring-rods (or chains) must be arranged accurately in the vertical plane passing through the terminal points of the base ; 2, the temperature of the rods must be observed at the time they are applied, and their rate of expansion determined by direct experiment, in order that the apparent lengths may be reduced to the length at a given temperature ; 3, they must be supported in such a manner as to have no tendency to flexure ; and 4, each rod, when adjusted in the line of the base, must be exactly horizontal, or its inclination exactly determined by levels, in order that the corresponding horizontal distance may be computed.

Previously to General Roy's measure of the base on Hounslow Heath the measuring apparatus used in all similar operations (with the exception of one of the bases measured by Lacaille and Cassini in France) consisted of deal rods, usually about 20 feet in length ; but deal rods, however well seasoned, are found to be considerably affected by the hygrometrical state of the air, and liable to sudden and irregular expansions and contractions, the effects of which cannot be accurately estimated, even when they are compared from time to time with a standard metallic bar. For this reason General Roy, after he had measured the base with deal rods, measured it a second time with hollow glass tubes. The tubes were 20 feet in length and about an inch in diameter, and the extremities were defined by metal buttons, ground perfectly flat, and perpendicular to the axis of the tube. At one end this apparatus was fixed to the tube ; at the other it was attached to a sort of piston, or slider, capable of being pushed up a certain way within the tube against a slender spring. A fine line marked on the slider, and another on the glass tube, were so adjusted, that when the slider was pushed up until the lines came into coincidence (which was observed through the glass), the distance between the flat ends of the metal buttons was exactly 20 feet at the temperature of 62° Fahr. In making the contacts, the flat end of one rod was pressed by a screw apparatus against the moveable end of the other, until the coincidence of the lines took place ; so that a constant pressure was applied equal to the tension of the spring. When the Ordnance survey was begun, this base was again measured with a steel chain, made by Ramsden, of 100 feet in length, and consisting of 40 links, terminated by a brass handle at each end. When in use the chain was supported on wooden coffers, raised on trestles, and stretched with a weight of fifty six pounds. The extremities were defined by marks on the brass handles ; and in order to bring the marks successively to the same point on the base-line the following contrivance was adopted : a brass scale, firmly secured to a post driven into the ground, but not connected with the chain or its supports, was placed contiguous to the preceding end, A, and adjusted by means of a screw apparatus, so that a division on the scale coincided exactly with the mark on the handle. The chain was then carried forward one length ; and when again placed on the coffers, was drawn back against the stretching-weight, until the mark on the handle at the following end, B, coincided with a division of the scale which had remained fixed in its place. In this manner the marks on A and B either occupied the same point on the line of the base, or the distance between them was known in terms of the scale. The same method was followed in measuring several other bases in England in the course of the survey, the chain being compared before and after each operation with another similar chain which was kept for this purpose. The advantage of the chain depends solely on its great length, by reason of which the number of coincidences (in making which the chief difficulty consists) is considerably reduced ; but this advantage is probably more than counterbalanced by its liability to alteration from wearing or corroding at the joints, and the insufficient security afforded that, notwithstanding the stretching, all its points are in the same straight line. The use of the chain has been confined to the English and Indian surveys, and is now abandoned in both.

The apparatus used by Delambre and Méchain in measuring the two bases in France, on which the length of the meridian depends, was constructed as follows :—The measuring rod was a thin bar of platinum, two toises in length, half an inch in breadth, and two lines in thickness. This was covered by another bar of copper, somewhat shorter, the two being firmly connected by screws at one end, but free at every other point, so that the expansions and contractions of each were not affected by the other. The relative expansions were thus indicated by the distance between the free extremities of the two bars ; for measuring which a finely divided scale was cut on a part of the platinum bar, and a vernier attached to the extremity of the copper bar. The relative expansion gave the means of computing the absolute expansion of the platinum bar at the time of the measurement. Four of these compound bars were used together ; and when all were adjusted in the line of the base, and the requisite observations made and recorded, the last was carried forward and placed first, the others being left in their places. The ends were not brought into contact ; a small interval was left between each and the next, which was measured by a slider, or small scale of platinum, attached to that end of the platinum-bar which was not covered by the copper bar. For the measure of the Hanoverian base Gauss employed three bars of hammered iron, two toises in length, and about an inch and a half in breadth and thickness, enclosed in boxes so as to leave only the ends projecting, and supported by counterpoises to prevent flexure. The ends were covered with steel plates, one flat and the other spherical ; and when the bars were placed in the line of the base, a small interval was left between the flat end of one bar and the spherical end of the preceding one, which was measured by dropping into it a thin wedge. Struve also employed iron bars in measuring the Russia base. In this case, however, the ends of the bars were brought into contact, and the contacts made on a principle similar to that which had been adopted by General Roy in using the glass rods. But the apparatus which formed the moveable extremity of Struve's rod consisted of a bent lever which turned on an axis passing through the bar, near its extremity, the motion of the short arm of the lever being in the direction of the length of the bar. The short arm terminated in a hemisphere which projected a little beyond the end of the bar ; and in making the contacts, the flat and fixed end of the next bar was pressed against the hemisphere, until an index on the extremity of the long arm of the lever stood at the middle of a scale connected with the bar, in which position the distance between the plane in which the bar terminated at one end, and the apex of the hemisphere at the other end, was exactly two toises at the normal temperature. A steel spring acting on the long arm of the lever regulated the degree of pressure applied in making the contacts.

In measuring the Prussia base Bessel used four compound bars constructed on the same principle as those of Delambre. The apparatus, which is simple and ingenious, will be readily understood from the annexed figure, in which the two ends are shown. $i\,i'$ is a bar of iron two toises in length, an inch broad, and a quarter of an inch thick $z\,z'$ is a bar of zinc of the same thickness and half the breadth. The two bars are firmly connected by screws and soldering at the end $z\,i$. The zinc bar $z\,z'$ terminates in two knife-edges of steel, the edges being horizontal. $k\,k'$ is a part of the iron bar, terminating in knife-edges, which are placed vertically, or at right angles to the former. The length of the measuring bar, or two toises at the normal temperature, is defined by the knife-edges at z and k' ; while the interval between z' and k varies with the temperature, and indicates the relative expansion, from which the absolute expansion of the iron bar becomes known. This interval was measured by inserting a thin glass wedge between the knife-edges ; and when the bars were placed in the line of the base, the interval between the knife-edge k' of one bar and z of the adjacent one was measured in the same manner. By means of fine divisions on the parallel sides of the glass wedges an interval in the direction of the base so small as the 12,000th part of an inch was made visible.

Fig. 1.



For the measurement of the Irish base an apparatus was employed by Colonel Colby in which the expansion of the measuring-rods was compensated in such a manner that no reduction was required on account of variations of temperature. The principle of this very ingenious apparatus will be understood from the following description :—A B is a brass bar, 10 feet in length. C D a bar of iron, firmly connected with the former at the middle E. Two steel tongues A P, B Q, are connected with the extremities of the bars by double conical joints which allow sufficient play to the tongues to prevent interference with the free expansions of the bars. At a certain normal temperature the steel tongues are perpendicular to the direction of the bars. Suppose them in this position, and that an increase of temperature takes place : the brass bar will become longer than the iron bar in consequence of its greater relative expansion, and a straight line A C P (on the middle of the tongue) will come into the position a c P, intersecting its former direction at a point P, so situated that P C has to P A the ratio of the expansion of the iron bar to that of the brass bar. But this ratio being constant, P is a given point ; and as the corresponding point Q on the other tongue is in precisely the same circumstances, it follows that the distance between P and Q will remain unaltered in all temperatures, provided at least both bars have the same temperature. This invariability is, however, not absolute, for when the tongue comes into the oblique position a P is longer than A P, and consequently the point marked on the tongue will be between a and the invariable point. Hence an increase of temperature must increase the distance between

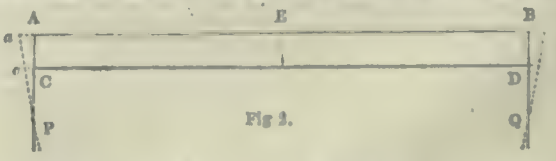


Fig 2.

P and Q: but the effect is insensible. The distance between the two bars was about 2 inches, and the distance of P from the iron bar or P O (which was determined experimentally) about 3½ inches. The bars were enclosed in strong wooden cases, having only the ends of the steel tongues exposed, and the cases laid upon trestles. Five or six sets of bars were used together; and when levelled and adjusted in the line of the base, the interval between the point Q on one set, and the point P on the next, instead of being variable (as in the methods of Delambre and Bessel), was made equal to a given constant quantity. This was effected by means of a microscopic apparatus, constructed on the same principle as the measuring apparatus, two microscopes taking the place of the steel tongues, and their foci being the points whose distance remains invariable. The microscopes were 6 inches apart, and between them, at the same distance from each, was a small telescope invariably connected with the two metallic bars, to which the microscopes were attached; the whole being so disposed that the three optical axes were in the same plane, and parallel to each other at the normal temperature. This apparatus being placed parallel to the line of the base, over the end of one of the sets of measuring bars, in such a manner that the point Q on the steel tongue was bisected by the cross-wires of one of the microscopes, the next set of bars was moved backwards or forwards until the point P was bisected by the cross-wires of the other microscope. A very delicate level fixed on the upper bar of the microscopic apparatus gave the means of adjusting the optical axis of the telescope exactly in the vertical; by which means, when it was necessary to suspend the operations, or to change the level of the line of the base, the point from which the measurement was to be resumed could be determined with much greater precision than by the usual means of a plummet. The measuring-bars were compared (daily, we believe) with a standard iron bar, which therefore is the unit of the distances; and the interval between the foci of the microscopes was in like manner verified by comparison with a scale.

The question of superiority among these different modes of measuring a base must be decided with reference to practical convenience: it cannot be affirmed that the results of any one of them are decidedly more accurate than those of the others. Col. Colby's apparatus is exceedingly beautiful in theory, but the play of the joints by which the tongues are connected with the bars, and the uncertainty there must be about the determination of the invariable points, and that their distance remains unaltered while changes of temperature are taking place, are obvious disadvantages. Bessel's apparatus is the most compact, and in fewest pieces; and we should imagine that his mode of measuring the intervals between the successive bars would be found easier in practice than making the distance between them constant. On the other hand, the adjustment of a point under the focus of a microscope is an operation which can probably be executed with greater precision than the measurement of the distance between two solid bodies, whether by a scale and vernier, according to the method of Delambre, or by a finely-divided wedge, as used by Gauss and Bessel.

The length of the base is a matter of some importance. Theoretically speaking, it cannot be too long. If a distance on the earth's surface (an arc or meridian, for example) deduced from a trigonometrical operation be m times the length of the base, then, putting errors of observations and calculation out of view, the probable error in the distance is to the probable error of the base in the ratio of $\sqrt{m} : 1$; consequently the longer the base the less is the probable error of the result. On the other hand, the probable error in the measurement of the base increases as the square root of its length; so that a distance deduced from a base of three miles measured only once would have as great a probable error as if it had been deduced from a base of only one mile measured three times, and the mean result taken as its true length. The bases measured in connection with the British survey, vary in length from 4·6 miles to about 8 miles. In the Indian survey the bases averaged about 7 miles. The two bases at Melun and Perpignan, on which the great French arc of meridian depends, were both upwards of 7 miles, and each consisted of two parts inclined to each other. In the Irish base 8 miles were directly measured with the compensation bars, and 2 miles were added by triangulation. Struve's base was 2315 toises, or about 2·8 miles. The Prussian base, measured by Bessel, was only 935 toises, or about 1⅛ mile. Baron Zach, who measured some small bases in Italy, contends that long bases, such as were measured in the French, English, and Indian surveys, are attended with no advantages corresponding to the expense they occasion; and Professor Schwerd, in an interesting account of a base of 2818 feet, measured by him near Spire, reasons to the same effect. ('Die Kleine Speyerer Basis,' Speyer, 1822.) Although we cannot subscribe to these opinions, it must be admitted that as instruments and the methods of observing and computing the observations have been improved, the necessity for frequent verification by the measure of new bases has been proportionably diminished.

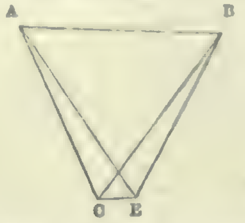
When the measuring-rods have been applied to the whole line of the base, and the proper reductions made for expansion, inclination, &c., the distance is obtained between the terminal points, in terms of the standard to which the measuring-rods are referred, on an arc of a great circle of the earth. In order that the results of different surveys may be comparable with each other, this circle must have a determinate radius; and hence it is usual to substitute for the arc actually measured, the corresponding arc on the surface which coincides with the mean level of the sea. Let l denote the measured length of the base, l' its length reduced to the mean level of the sea, h its height above that level, and r the radius of the earth: the l' is found from this proportion, $r+h : r :: l : l'$.

Triangulation.—In commencing the Triangulation, the first step is to make choice of the points or stations which are to form the summits of the principal triangles. The choice of stations must be determined in some measure by the nature of the country, and with reference to the objects of the survey; but care must be taken to avoid very acute angles, because small errors in the measurement of such angles will give rise to large errors in the lengths of the sides deduced from them. The best-conditioned triangles are those which are nearly equilateral. The principal triangles should be of considerable magnitude, for the probable error of a distance deduced from a base through a series of triangles increases with the number of intermediate triangles. Sides averaging from 20 to 50 miles may be considered as the most convenient; but in mountainous countries, or for connecting stations separated by the sea, the magnitude of the triangles will sometimes be limited only by the distance at which the signals cease to be visible from each other. When the object of the survey is the topography of the country, the geographical positions (the latitudes, longitudes, and altitudes above the sea), as well as the mutual distances of these primary stations, should be determined with all the precision it is possible to attain. The more remarkable features of the country are afterwards connected with the principal stations, by *secondary* triangles, which, being liable only to small relative errors, may be determined more expeditiously by less precise observations or with inferior instruments; and the intermediate points are filled in by means of the surveyor's compass and chain. [SURVEYING.]

Signals.—When the stations have been chosen, the next point to be considered is the erection of signals. In the earlier surveys, the usual practice was to select such conspicuous objects as the country presented, as church spires, windmills, &c.; but experience has shown that objects of this kind, even when found (which will seldom be the case) in those positions where it is desirable that the angular points of the triangles should be established, are not well adapted for signals, and that in general the most advantageous course is to construct them for the express purpose. In the earlier part of the English survey, the observations were chiefly made by night, and the signals were reverberatory lamps with concave metallic reflectors supported by flagstaffs, and enclosed in tin cases, having plates of glass in front to screen the light from the action of the wind. Such signals answer well enough for distances under 30 miles. Biot and Arago, in the prolongation of the French arc of meridian, also employed reverberatory lamps and concave reflectors; and in one case the distance between the station and the signal exceeded 100 miles. Bengal lights, blue-lights, and other contrivances have also been used as night-signals. Delambre constructed his signals of wood in the form of truncated four-sided pyramids, and observed by day. For the large triangles in Ireland and the west of Scotland, Colonel Colby built up conical piles of dry stone, which were thrown down when the instrument was taken to the spot, and again built up when it was necessary to observe the same signal from other stations. Such signals were found to be visible in the telescope of the great theodolite at the distance of 90 or 100 miles in favourable weather. Plates of polished metal, placed so as to reflect the light of the sun in the proper direction, have been found a powerful means of rendering a station visible. Gauss proposed the heliotrope, in which the reflecting surface is silvered glass; and this was the signal which was principally used by Struve and Bessel. Another method, adopted by Bessel for short distances, was the reflexion of light from a hemisphere of polished copper. These two last methods have the disadvantage of rendering the observer dependent on sunshine, but in other respects they afford excellent signals, for as the light proceeds from a point, the observation is made with the greatest precision. In the case of the hemisphere indeed, the luminous point is not in the axis of the signal, but as the radius of the hemisphere and the azimuth of the sun at the time of the observation are known, its position with reference to the axis can be accurately computed, and a correction applied if the deviation is sensible. But all solid bodies used as signals render a similar correction necessary when the light falls upon them obliquely. To avoid this inconvenience, Svanberg observed the light of the sky through a rectangular opening in a blackened board which turned about a vertical axis, so that its plane could always be placed perpendicular to the visual ray. Night-signals are found inconvenient by reason of the unsteadiness and the scintillations of the light; and accordingly geodetical observations are now generally made by day; nevertheless, under peculiar circumstances, night observations may be advantageous, or even necessary. Thus, in India, Colonel Everest found that the greater refraction during the night sometimes rendered stations visible which could not be seen by day, being hid by the intervening ground.

With respect to instruments and the methods of observing in geodetical surveys, ample information is given in the articles THEODOLITE, REPEATING CIRCLE, &c. We may here remark, however, that as each signal (speaking generally) is the common vertex of several triangles, an angle required for the calculation of a triangle may frequently be obtained from the sum or difference of other angles at the same point, as well as by direct observation. This circumstance permits the observations to be made in various ways, and affords an important means of verification; but in order that full advantage may be derived from it, the observations must be made and combined according to some systematic plan. Struve, in the Russian triangulation, adopted the plan of observing successively the direction of every signal visible from his station, in reference to a certain arbitrary direction; and the same method was followed by Bessel. This appears to be the mode of conducting the observations by which an observer is enabled to make the most of his position.

Reduction to the Centre of the Station.—It is desirable that the centre of the instrument should always be placed in the vertical line which coincides with the axis of the signal at the same station; but the strict fulfilment of this condition may sometimes be impossible, or at least extremely inconvenient. In such cases the instrument is placed near the station, and a correction made for the excentricity. Let C be the centre of the station, E the place where the instrument is placed, A and B the distant signals, so that ACB is the angle which is required, and AEB the angle actually measured. Let the distance CE be denoted by d, and AC (computed approximately) by m; then the difference, in seconds, between ACB and AEB is found from this formula—



$$ACB - AEB = \omega\, d \sin(BAC - BEC) \div m \sin BAC,$$

where $\omega = 206264{\cdot}8''$, the number of seconds in an arc equal to the radius, or $\omega = \operatorname{cosec} 1'' = 1 \div \sin 1''$.

Reduction to the Horizon.—Although the theodolite has now come into general, perhaps universal use, in carrying on important geodetical operations, we shall add the formula by which an angle measured in the oblique plane passing through the instrument and the two observed objects is reduced to the horizon. Let A and B be the remote signals, C the angle in the oblique plane, C′ its projection on the plane of the horizon; and let α and β denote respectively the number of seconds by which A and B are observed to be elevated or depressed above or below the horizon of C; then

$$C - C' = \left\{ \tfrac{1}{4} (\alpha+\beta)^2 \tan \tfrac{1}{2} C - \tfrac{1}{4} (\alpha-\beta)^2 \cot \tfrac{1}{2} C \right\} \sin 1''.$$

When the angles have been measured, and (if necessary) deduced to the centre of the station and the horizon, their values as given by the instrument, being all affected with some portion of error which it is impossible by any means to get rid of, must undergo a process of correction or adjustment, or be made to satisfy certain mathematical conditions, before a determinate result can be deduced from them. In order to establish these conditions the following quantity must be computed for every triangle in the series.

Spherical Excess.—The spherical excess of a triangle on the surface of a sphere or spheroid, formed by the sections of planes perpendicular to the surfaces, is the excess of the sum of its three angles over 180°. This excess has a given relation to the area of the triangle depending upon the radius of the sphere; and in a geodetical survey the data for computing it are, in every case, a side c, and the three observed angles A, B, C, of which C is supposed opposite to c. Let S denote the number of square feet in the surface or area of the triangle, E the spherical excess in seconds, and r the radius of curvature in feet; we have then $S = \frac{1}{2} cc \sin A \sin B \div \sin C$, and $E = \omega S \div rr$, where $\omega = 206264{\cdot}8''$.

On the spheroid, the radius of curvature of a section perpendicular to the surface is variable, and depends both on the latitude and the inclination of the section to the meridian. For a series of triangles included between two parallels of latitude whose distance is not more than two or three degrees, r may be supposed constant in computing the spherical excess; and as the nearest approximation to its mean value, we may take the radius of curvature of the section which intersects the meridian in an angle of 45°, at the middle latitude. The general formula for the radius of curvature of an oblique section is

$$\frac{1}{r} = \frac{(1 - ee + ee \cos^2 l \cos^2 \theta) \sqrt{(1 - ee \sin^2 l)}}{a(1 - ee)}$$

where a is the radius of the equator, e the excentricity (so that $ee = (aa - bb) \div aa$, b being half the polar axis), l the latitude, and θ the azimuth, or inclination of the section to the meridian.

Let ρ denote the radius of curvature of the meridian (for which $\theta = 0$), ρ' that of the section perpendicular to the meridian (for which $\theta = 90°$), the formula gives

$$\frac{1}{\rho} = \frac{\sqrt{(1 - ee \sin^2 l)^3}}{a(1 - ee)}; \quad \frac{1}{\rho'} = \frac{\sqrt{(1 - ee \sin^2 l)}}{a};$$

whence also

$$\frac{1}{r} = \frac{1}{\rho} \cos^2\theta + \frac{1}{\rho'} \sin^2\theta = \tfrac{1}{2}\left(\frac{1}{\rho} + \frac{1}{\rho'}\right) + \tfrac{1}{2}\left(\frac{1}{\rho} - \frac{1}{\rho'}\right) \cos 2\theta,$$

from which $1 \div r$ is readily computed for any value of θ. When $\theta = 45°$, the second term vanishes.

In the latitude of Greenwich (51° 28′ 39″), $\rho = 20911961$ feet, $\rho' = 20966473$ feet, whence (making $\theta = 45°$) $\log (\omega \div rr) = 0{\cdot}67251 - 10$, and consequently $\log E = \log S + 0{\cdot}67251 - 10$. In order that E may amount to 1″, we must have $\log S = 9{\cdot}39749$, or $S = 2{,}497{,}800{,}000$ square feet, or nearly 76½ square miles, that is to say, the spherical excess amounts to 1″ for every 76½ square miles in the area of the triangle. The calculation of the area therefore does not require to be made with much accuracy, and may be facilitated by means of subsidiary tables.

Correction of the Observations.—One of the improvements for which practical geodesy has recently been indebted to the German astronomers, particularly Gauss and Bessel, is a general method of combining and correcting the observations according to the principles of the theory of probability, so as to elicit the result which is *most probably* nearest the truth, or which gives the nearest representation of the whole of the observations. Formerly the practice was to regard each triangle as a complete and independent whole, and to adjust the observed angles (usually by some arbitrary process, or according to the observer's judgment of their relative goodness), so as to fulfil the condition of their sum being equal to 180° together with the spherical excess, without regard to the relations subsisting among the angles of the quadrilaterals or other polygons formed by the lines connecting the angular points. But this mode of proceeding affords a very imperfect solution of the problem: for in order to obtain the best result which can be deduced from the observations, it is indispensable to have regard not only to the condition just named, but to every independent relation subsisting among the angles of the whole series of triangles included in the survey; and the more numerous the relations are which the observations are made to satisfy, the greater will be the probable accuracy of the final result.

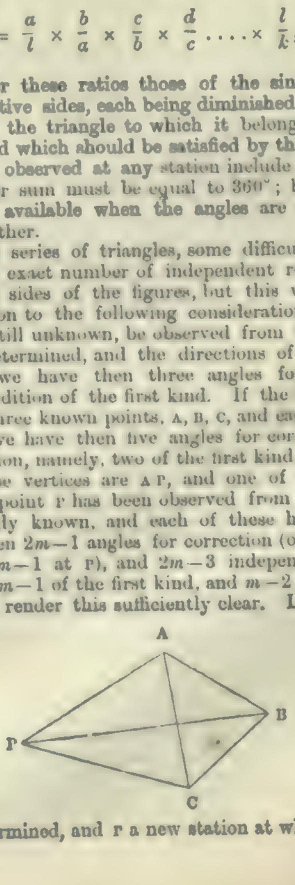
The equations of condition which express the independent relations connecting the angles of a system of geodetical triangles arise chiefly from three sources: 1, The sum of the three angles of each triangle is equal to 180° *plus* the spherical excess; which excess, being in all cases a very small quantity, can be computed to so great a degree of accuracy, that it may be regarded as absolutely exact. 2, If there be a system of triangles so connected that the second has a side a in common with the first, the third a side b in common with the second, the fourth a side c in common with the third, and so on to the last, which has a side k in common with the preceding one, and another side l in common with the first, then, on forming the identical equation

$$1 = \frac{a}{l} \times \frac{b}{a} \times \frac{c}{b} \times \frac{d}{c} \cdots\cdots \times \frac{l}{k},$$

and substituting for these ratios those of the sines of the angles opposite the respective sides, each being diminished by a third of the spherical excess of the triangle to which it belongs, an equation of condition is obtained which should be satisfied by the observed angles. 3, When the angles observed at any station include the whole circuit of the horizon, their sum must be equal to 360°; but this condition can only be made available when the angles are determined independently of each other.

In a complicated series of triangles, some difficulty may be found in determining the exact number of independent relations furnished by the angles and sides of the figures, but this will be materially lessened by attention to the following considerations: If a point, P, whose position is still unknown, be observed from two other points, A and B, already determined, and the directions of A and B be also observed from P, we have then three angles for correction, and one equation of condition of the first kind. If the unknown point, P, be observed from three known points, A, B, C, and each of these be also observed from P, we have then five angles for correction, and three equations of condition, namely, two of the first kind, furnished by the two triangles whose vertices are AP, and one of the second: and, generally, when a point P has been observed from m stations whose positions are already known, and each of these has been observed from P, we have then $2m-1$ angles for correction (one at each of the given points and $m-1$ at P), and $2m-3$ independent equations of condition, namely, $m-1$ of the first kind, and $m-2$ of the second.

An example will render this sufficiently clear. Let A, B, C be three points already determined, and P a new station at which the directions



of A, B, and C have been observed, and which has itself been observed from those points. These observations give five independent angles to be corrected, namely, two at P, and one at each of the other stations, and three equations of condition, which are thus found: the two triangles APC and BPC give two equations of the first kind, namely,

$$1,\ \mathrm{APC}+\mathrm{PAC}+\mathrm{ACP}=180^\circ+\mathrm{E},$$
$$2,\ \mathrm{BPC}+\mathrm{PBC}+\mathrm{BCP}=180^\circ+\mathrm{E}'.$$

On considering the three triangles APB, BPC, ABC, it will be seen that the side PB is common to the first and second, BC to the second and third, and AB to the third and first. Forming therefore the identical equation

$$1=\frac{\mathrm{PB}}{\mathrm{AB}}\cdot\frac{\mathrm{BC}}{\mathrm{PB}}\cdot\frac{\mathrm{AB}}{\mathrm{BC}},$$

and substituting for those ratios those of the sines of the opposite angles (each diminished by one-third of the spherical excess), we get the equation of the second kind:—

$$3,\ 1=\frac{\sin\mathrm{PAB}}{\sin\mathrm{APB}}\cdot\frac{\sin\mathrm{BPC}}{\sin\mathrm{BCP}}\cdot\frac{\sin\mathrm{ACB}}{\sin\mathrm{CAB}}.$$

When the equations of condition have been thus formed, the observed values of the different angles are substituted in them, each being increased or diminished by a small indeterminate correction. The values of the corrections are then determined simultaneously by solving the equations according to the method of *minimum squares*, or so that the equations of condition shall be satisfied as nearly as possible (they cannot be all satisfied exactly), and the sum of the squares of the corrections shall be a minimum. For further details on this subject, and examples of the application of the theory to trigonometrical surveys, we must content ourselves with a reference to the 'Supplementum Theoriæ Combinationis,' &c. of Gauss (Göttingen, 1828), where it is applied to a portion of the triangles surveyed by Krayenhoff in Holland; to Nos. 121 and 122 of the 'Astron. Nachrichten,' where it is applied by Rosenberger to Maupertuis's measurement in Sweden; to No. 438 of the same work, where it is applied by Bessel to the computation of the triangles at the southern extremity of the French arc of meridian: and to the 'Gradmessung in Ost-Preussen,' already referred to. The advantages of the method are two-fold. In the first place there is the probability that the result is *nearer* the truth than if it had been deduced in any other way; and secondly, a general and uniform process of calculation is substituted for an imperfect and arbitrary one.

In proceeding according to the ordinary method, and regarding the triangles as independent of each other, the process is much simpler. The difference between the sum of the three observed angles and 180° + E is the aggregate error of the three determinations. If each angle was determined by an equal number of equally good observations, the probable error would be the same for each, and the correction would be properly made by dividing the aggregate error equally among the three. If the observations are assumed to be equally good, but each of the angles has been determined by a different number, then the portion of the aggregate error which should be thrown upon each angle is reciprocally proportional to the number of observations by which it was determined; but when the individual observations are not equally good (and this is the general case) the distribution of the aggregate error should be made in such a manner that the amount of the correction to be applied to each angle is proportional directly to the sum of the squares of the differences between each observation and the arithmetical mean of the whole, and inversely as the square of the number of observations by which the angle was determined. If an angle has been determined by a single reading, the portion of the aggregate error to be assigned to it may be made proportional to the *mean square* (that is, the sum of the squares of the differences from the mean divided by the number of observations) of the errors of a series of observations at one of the other angles made under similar atmospheric circumstances. Such is the method which the theory of probable errors indicates; but in most of the geodetical surveys which have yet been published, the distribution of the aggregate error among the three angles has been made, as already remarked, according to some arbitrary hypothesis.

The three angles of the triangle, corrected in the manner now described, are regarded as the true geodetical angles, or rather as the spherical angles formed by the arcs of the great circles which intersect in the verticals passing through the stations on the surface of the osculating sphere. In strictness there are no practical means of determining the true geodetical angles, that is, the angles made by the shortest lines on the spheroid. The observed angle is not the geodetical angle, but the angle made by the two planes which intersect in the vertical of the station, and pass through the remote signals.

Calculation of the Sides.—The method of computing the sides which first suggests itself is, to convert the given or known side into degrees of a circular arc, whose radius is equal to that of the earth, and apply the formulæ of spherical trigonometry. This method has been sometimes adopted; but as it gives rise to tedious calculations, it is usual to have recourse to more expeditious processes, which, though only approximative, give equally exact results. Various methods of approximation have been proposed, though there are only two which have been much used. One of them is the method which has been exclusively followed in the Ordnance survey, so far as published, and also, generally by Delambre. It consists in deducing from the spherical angles the corresponding angles formed by the chords, and then computing the triangle by plane trigonometry. In this manner the chords of the two unknown sides are found, from which the sides themselves are easily deduced. The formulæ are as follows:—

Let the three spherical angles (that is, the observed angles corrected for the errors of observation) be denoted by A, B, C; the sides respectively opposite by a, b, c (expressed in feet); and the radius of curvature of the surface by r (also in feet). Let A′ be the angle formed by the chords of the sides b and c, and suppose $\mathrm{A}-\mathrm{A}'=x$ seconds; then putting $\omega=206264{\cdot}8''$,

$$x=\frac{\omega}{16}\left(\frac{b+c}{r}\right)^2\tan\tfrac{1}{2}\mathrm{A}-\frac{\omega}{16}\left(\frac{b-c}{r}\right)^2\cot\tfrac{1}{2}\mathrm{A}.$$

In like manner if B′ and C′ denote the chord angles corresponding to the spherical angles B, C, respectively, and if we suppose $\mathrm{B}-\mathrm{B}'=x'$ and $\mathrm{C}-\mathrm{C}'=x''$, the two small corrections x' and x'' will be computed from similar expressions to the above, and we have then the three plane angles A′, B′, C′, the sum of which is 180°. For computing these corrections approximate values of the sides must be previously found; but for this purpose it will generally be sufficient to use logarithms to four decimal places.

Although for facility of explanation we have described the reduction to the chord angles as applied to the corrected spherical angles, it is manifest that it may be (in practice it generally is) applied to the observed angles. In this case we get $\mathrm{A}'+\mathrm{B}'+\mathrm{C}'=180^\circ\pm$ the aggregate error of the three observed angles, which error must be then distributed among the three reduced or chord angles in the manner before described, so that their sum may be exactly 180°. By this means, since we have obviously $x+x'+x''=\mathrm{E}$, the previous calculation of the spherical excess, in order to correct the observations, is rendered unnecessary.

When the chords have been computed from the reduced angles A′ B′, C′, the arcs are found in terms of the chords by a well-known series, of which it is only necessary to use the two first terms. Let a be a small arc, and a' its chord, then $a=a'-(a'^3\div 24r^2)$.

The other method of computing the sides to which we have alluded depends on the following theorem, which was first given by Legendre. If from each of the angles of a spherical (or spheroidical) triangle, the sides of which are small in comparison of the radius, one-third of the spherical excess be deducted, the sines of the angles thus diminished will be proportional to the lengths of the opposite sides, so that the triangle may be computed as in plane trigonometry. As before, let A B, C be the corrected spherical angles, a, b, c the sides respectively opposite, and E the spherical excess; then, if we make

$$\mathrm{A}'=\mathrm{A}-\tfrac{1}{3}\mathrm{E},\ \mathrm{B}'=\mathrm{B}-\tfrac{1}{3}\mathrm{E},\ \mathrm{C}'=\mathrm{C}-\tfrac{1}{3}\mathrm{E},$$

we shall have, in virtue of the theorem,

$$b=\frac{a\sin\mathrm{B}'}{\sin\mathrm{A}'},\ c=\frac{a\sin\mathrm{C}'}{\sin\mathrm{A}'},$$

from which formulæ the sides b and c are computed. This method therefore requires no greater amount of calculation than would be necessary if the triangles were on a plane surface, excepting that of the spherical excess; and if the three angles are assumed to be determined with equal accuracy, even this is not wanted (unless for the purpose of testing the accuracy of the observations), the angles for calculations being found at once by applying to each of the three observed angles a third of the difference between their sum and 180°. This is the method which is most frequently adopted.

Legendre's theorem will give a sufficiently accurate result in ordinary cases; but if the triangles are very large, and the utmost precision is aimed at, it will sometimes be desirable to have a closer approximation. This may be obtained by computing the angles A′, B′, C′ from the following expressions of their values, which appear to have been first given by Professor Buzengeiger, in Lindenau's 'Zeitschrift für Astronomie,' vol. vi. (Tübingen, 1818), and which are equivalent to an extension of the theorem so as to include terms of the second order, Legendre's approximation including only those of the first. As before, let S be the area of the triangle, and $\omega=206264''{\cdot}8$, then

$$\mathrm{A}-\mathrm{A}'=\frac{\omega\mathrm{S}}{3rr}\left(1+\frac{aa+7bb+7cc}{120rr}\right),$$
$$\mathrm{B}-\mathrm{B}'=\frac{\omega\mathrm{S}}{3rr}\left(1+\frac{7aa+bb+7cc}{120rr}\right),$$
$$\mathrm{C}-\mathrm{C}'=\frac{\omega\mathrm{S}}{3rr}\left(1+\frac{7aa+7bb+cc}{120rr}\right),$$

and in consequence of these, the spherical excess $\mathrm{E}\,(=\mathrm{A}+\mathrm{B}+\mathrm{C}-180^\circ)$ becomes

$$\mathrm{E}=\frac{\omega\mathrm{S}}{rr}\left(1+\frac{aa+bb+cc}{24rr}\right).$$

It is easy to see that the second terms of these expressions must always be very small; in fact, they will amount only to a few hundredths of a second even in the largest triangles. Nevertheless when the angles are considered as having a mutual dependence, and the corrections for a whole series are determined simultaneously from the equations of condition, the corrected angles will be given (if great precision is required) to three or four decimals of a second, and the above formulæ will have a practical application. They were used by Bessel in the recalculation of the triangles at the southern extremity of the French arc of meridian; and we give them a place the more willingly as they have not hitherto, so far as we know, found their way into any English work.

Professor Buzengeiger has also given a formula for the calculation of the sides of a geodetical triangle, which may be substituted for the method of Legendre, or used for verification. Let a be the known side, A, B, C, the corrected spherical angles, $m = 0{\cdot}4342945$, the modulus of the common logarithms, and $n = m \div 3\omega = 0{\cdot}0000007$, then for computing b and c we have

$$\log b = \log a + \log \sin \mathrm{B} - \log \sin \mathrm{A} + n\,\mathrm{E}\,(\cot \mathrm{A} - \cot \mathrm{B});$$
$$\log c = \log a + \log \sin \mathrm{C} - \log \sin \mathrm{A} + n\,\mathrm{E}\,(\cot \mathrm{A} - \cot \mathrm{C}).$$

With the help of a small table of natural tangents, this method is scarcely more troublesome than Legendre's. The chord method is more tedious than either, and does not appear to be attended with any corresponding advantage.

Latitudes, Longitudes, and Azimuth.—Having ascertained the terrestrial distances between the several stations, the next step is to determine their geographical positions, or situations with respect to the equator and an assumed first meridian. For this purpose the latitude and longitude of one station at least, and the azimuth of a side of one of the triangles, must be accurately determined by astronomical means; we have then the data that are necessary for computing the geographical position of every other angular point, and the bearing of every other side, through the whole series of triangles, assuming the earth to be a spheroid of rotation of known dimensions and ellipticity. The uncertainty, however, which always exists respecting the exact form and curvature of any particular portion of the earth's surface, or rather the irregularities of local configuration, require independent astronomical observations, particularly of azimuth, to be made at more stations than one, when the triangulation extends over a considerable tract of country.

If the country included in the survey contains a fixed observatory, this will of course either form one of the principal stations or be connected with the principal triangles, and may be taken as the point of departure. In this case the astronomical position of the fundamental point is known with the greatest certainty; and the meridian-mark of the transit-instrument affords the surest means of determining the bearing of any signal visible from the observatory. At any other station the best method of determining the azimuth is probably to imitate this proceeding, by setting up a temporary mark as nearly in the meridian as may be, and determining its deviation with a transit-instrument by some of the methods used in practical astronomy for the purpose. [TRANSIT-INSTRUMENT.] The angle between the mark and the signal at another of the principal stations is then measured with the theodolite, whence the azimuth of the signal becomes known. But as this method cannot always be conveniently followed in geodetical operations, the usual practice is to make the surveying instrument itself subservient to the determination of azimuths. In the English survey the method commonly adopted was, to observe with the theodolite the angle between a flag-staff and the pole-star at its extreme digressions east and west, and to take half the sum of the two angles as the azimuth of the staff. In determining the azimuth in this way a very accurate adjustment of the instrument is necessary. The method usually followed on the Continent has been to observe the angle between a referring signal and the sun, or some star whose place is well known, when near the horizon; and as the azimuth of the sun or star at a given instant of time can be computed with great precision, the observation is liable to no particular cause of error, unless in the determination of the exact clock-time. The result is usually made to depend on the mean of a great number of observations.

The problem on the solution of which the calculation of the geodetical latitudes and longitudes of the stations, and the azimuths of the sides of the triangles, depends is this: Let A and B be two stations whose distance has been determined, and suppose the latitude and longitude of A to be known, together with the azimuth of B as seen from A; it is required to find the latitude and longitude of B, together with the azimuth of A as seen from B. The azimuthal angles are supposed to commence at the south point of the horizon, and to be reckoned towards the west (or right) from 0 to 360°. Assume

l = the latitude of A, l' = the latitude of B,
λ = the longitude of A, λ' = the longitude of B,
θ = the azimuth of AB at the station A,
θ' = the azimuth of AB at the station B,
d = the distance on the spheroid between A and B, in feet.

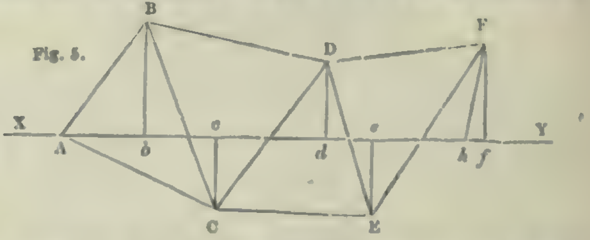
And, as before, let a denote half the greater axis of the meridian, e the excentricity, $\rho' = a \div \sqrt{(1 - ee \sin^2 l)}$, the radius of curvature of the arc perpendicular to the meridian at A, and $\omega = 206264''{\cdot}8$. Then, putting (for brevity) $u = d \div \rho'$, the differences of the latitudes, longitudes, and azimuths of the two stations, in seconds of arc, are given by the following formulæ, namely:—

$$l' - l = -\omega\,(u \cos\theta - \tfrac{1}{2}\,u^2 \sin^2\theta \tan l)\,(1 + ee \cos^2 l),$$
$$\lambda' - \lambda = \omega\,u \sin\theta \sec l',$$
$$\theta' - \theta = 180^\circ - (\lambda' - \lambda) \sin\tfrac{1}{2}(l' + l) \sec\tfrac{1}{2}(l' - l).$$

These formulæ are only approximative; but they are sufficiently exact for every case that can arise in practical geodesy. Even in the case of the greatest distances between the stations, 100 miles for example, the results which they give will agree with those which are computed from the exact formulæ of spheroidical trigonometry to within a small fraction of a second.

By means of the above formulæ, the geographical positions of the principal stations are successively deduced from each other; but when a chain of triangles runs nearly north and south, or east and west, the differences of latitude and longitude are more readily computed by referring the different stations to an assumed meridian by means of parallels and perpendiculars. Let A, B, C, D, E, F be the summits of a chain of triangles, and X Y the direction of the meridian passing through the first point A; and let perpendiculars Bb, Cc, &c., be drawn from each of the other points to X Y. Suppose the angle XAB (the azimuth of B on the horizon of A) to be determined by astronomical observations: then, as the angles at B, C, D, &c., are all known from the geodetical observations, the angles which the several sides of the triangles make with X Y are easily computed; and the distance on the meridian between the perpendiculars through the extremities of any side is found by multiplying the length of the side into the cosine of its inclination. Hence the distance on the meridian from the point of departure A, to the foot of the perpendicular through any other point, F, is equal to the sum of the sides which join A and F, each multiplied into the cosine of its inclination. Thus, the sum of the products of the three sides AB, BD, DF, by the cosines of their respective inclinations, gives Ab + $b$$d$ + $d$$f$ = Af; or the sides AC, CE, EF, reduced in the same manner, give Ac + $c$$e$ + $e$$f$ = Af. Hence the distance from A to the foot of the perpendicular through each point becomes known. In like manner, on multiplying the length of any side into the *sine* of its inclination, we have the difference of the distances of its two extremities from X Y, and the distance Ff, of any point F, is the sum of those differences (taken with their proper signs) in respect of all the intermediate sides between A and F. These relations are more shortly expressed by algebraic formulæ. Let the inclinations of three sides intermediate between A and F, for example, AB, BD, DF (the angles at the different points being all reckoned in the same direction), be respectively α, β, γ; then, attention being given to the algebraic signs of the trigonometrical lines, we have

Fig. 5.



$$\mathrm{A}f = \mathrm{AB}\cos\alpha + \mathrm{BD}\cos\beta + \mathrm{DF}\cos\gamma,$$
$$\mathrm{F}f = \mathrm{AB}\sin\alpha + \mathrm{BD}\sin\beta + \mathrm{DF}\sin\gamma.$$

By this means, all the angular points of the series are referred to the meridian of the first, exactly in the same manner as the different points of a curve are referred to its axis by their co-ordinates.

We have now to determine the differences of latitude. Taking the point F for example, let Fh be the arc of the parallel circle on the spheroid, passing through F, and h its intersection with the meridian of A, then Ah (which is always less than Af) is the arc of meridian corresponding to the difference of latitudes. To compute fh we have, from the properties of the spheroid, the formula $fh = \overline{\mathrm{F}f}^2 \tan l' \div 2\mathrm{R}$, in which l' is the approximate latitude of F, and R the distance from the centre of the earth; and as fh is always very small, instead of computing the value of R, it will be sufficiently accurate to use ρ, the radius of curvature of the meridian corresponding to the latitude. The distance fh thus found is expressed in feet; to convert it into seconds of arc we must multiply by $\omega \div \rho$; hence the difference of the latitudes of F and A, expressed in seconds, is—

$$l' - l = (\omega \div \rho)\;(\mathrm{A}f - fh).$$

The latitude of F and its distance Ff from the meridian of A being known, its longitude, or the arc Fh of the parallel circle, is found from the formula already given. Let ρ' be the radius of curvature of the perpendicular arc Ff, then $(\omega \div \rho')\,\mathrm{F}f$ is the number of seconds in Ff, and hence the difference of longitudes of F and A in seconds is—

$$\lambda' - \lambda = (\omega \div \rho') \times \mathrm{F}f \sec l'.$$

When the positions of a considerable number of points are to be determined, the calculations may be facilitated by forming a table of the values of fh corresponding to every value of Ff proceeding by small differences, 100 feet for example. In following this method, however, the stations must not be so far from the assumed meridian that the difference of the curvilinear distance and its projection on the horizontal plane becomes sensible, and hence in the survey of a large country the direction of a new meridian (or the azimuths) requires to be determined astronomically when the triangulation has been carried a degree or two to the east or west of the point of departure. It is scarcely necessary to add that the positions of the secondary points are computed without reference to the curvature, or convergence of meridians.

The method of computing the distance between the parallels of two remote stations, A and F, which we have now described, is that which is usually followed in measuring arcs of meridian. To this purpose, indeed, it is particularly adapted, for as the chain of triangles runs along the direction of the meridian, the distances of the signals from the line to be measured are not so great as to give rise to any error by reason of the neglect of the curvature of the perpendicular arc. For other methods of computing the parts of the meridian, and formulæ, theoretically more exact, for computing the latitudes, longitudes, and azimuths, see Delambre's 'Méthodes Analytiques pour la Determination d'un Arc du Méridien;' or Puissant, 'Traité de Géodésie,' third edition, 1842.

If the earth were a regular spheroid of rotation, the latitudes and longitudes deduced from geodetical measurements commencing with a given observatory would agree exactly (supposing no errors) with those given by astronomical observations. Such agreement however is not found to exist, and no regular figure can be assigned to the earth by which the results of the two methods can be entirely reconciled. An instance or two will suffice to give an idea of the extent to which the discordances may reach. In the remeasurement of Beccaria's arc, the astronomical difference of latitude between Andrate and Mondovi was found to be 1° 7′ 26″.98, while the difference computed from the French triangulation, taking the observatory of Paris as the point of departure, and assuming the ellipticity $=1 \div 308{\cdot}65$, was 1° 8′ 14″.82. The discordance amounts to 47″.84, corresponding to a distance on the meridian of about 4880 English feet, the whole distance being about 368,885 feet. Again, the latitude of Venice deduced from that of Rimini by triangulation was found to differ 17″.2 from the latitude given by direct observation; and the latitude of Rimini deduced from that of Milan differed 27″.4 from the astronomical latitude. ('Connaissance des Tems,' 1827.) Similar anomalies have been found in the surveys in England, France, Austria, and indeed all other countries; and as their amount exceeds that which can with any probability be assigned to errors of observation, they are ascribed to irregularities in the direction of gravity arising from inequalities in the form or internal structure of the earth,—to the attraction of mountains or local variations of density. Puissant ('Mém de l'Acad.,' t. xiv., 1838) shows reason for supposing that in France the curvature of the surface is considerably different on the east and west sides of the meridian of Paris.

Determination of the Altitudes.—In order to complete the description of the objects embraced in a trigonometrical survey, it only remains for us to point out the manner in which the relative heights of the stations are observed and computed. The observations required for this purpose are the zenith distances of the signals as seen from each other; and they may be made with the theodolite or any instrument with which angles can be measured in a vertical plane. The chief difficulty attending the determination arises from the uncertainty of the terrestrial refraction, an element which is liable to frequent and considerable variations, more especially as the objects observed are always nearer the horizon. The formulæ are as follows:—

Let h and h' denote respectively the heights of two stations, A and B, above the level of the sea; z the zenith distance of B as observed at A; Δz the seconds of arc through which B is elevated by the refraction; z' and $\Delta z'$, the corresponding quantities in respect of A as observed at B; C the angle at the centre of the earth formed by the verticals of A and B; d the distance in feet between A and B on the spheroid; and r the radius of curvature of the terrestrial arc. The plane triangle formed by the two verticals and the straight line which joins A and B gives this analogy:—

$$2r+h'+h : h'-h :: \cot \tfrac{1}{2} C : \tan \tfrac{1}{2} \left\{z'+\Delta z'-(z+\Delta z)\right\},$$

from which, on rejecting superfluous quantities, and with the aid of certain physical assumptions, the formulæ for computation are deduced.

In the first place, $h'+h$ may be rejected as being insensible in comparison of $2r$: then since $z'+\Delta z'-(z+\Delta z)=2\left\{90°-(z+\Delta z-\tfrac{1}{2}C)\right\}$, the above analogy gives

$$h'-h=2r \tan \tfrac{1}{2} C \cot (z+\Delta z-\tfrac{1}{2}C).$$

Again, because C is always a very small angle, we may put, without sensible error, $d=2r \tan \tfrac{1}{2} C$. The last formula then becomes

$$h'-h=d \cot (z+\Delta z-\tfrac{1}{2} C).$$

With respect to the unknown quantity Δz, two assumptions are made: first, it is assumed that the whole effect of the refraction at both stations is proportional to the distance between the stations, or to the angle C; or to assume $\Delta z'+\Delta z=kC$, where k is a numerical coefficient. Secondly, it is assumed that the effect of the refraction is the same at both stations, or that $\Delta z'=\Delta z$; this gives $\Delta z=\tfrac{1}{2}kC$, and consequently $\Delta z-\tfrac{1}{2} C=-\tfrac{1}{2}(1-k) C$. Substituting this in the last equation, we get

$$h'-h=d \cot \left\{z-\tfrac{1}{2}(1-k) C\right\} \qquad (a).$$

This equation gives the height of the signal at B above the place of the instrument at A in terms of the geodetical distance d, and the observed angle z, assuming the coefficient of refraction to be known. It will be observed that C is given in seconds by the formula $C=\omega d \div r$, where $\omega=206264''{\cdot}8$.

When the zenith distances are observed at both stations, the coefficient k may be deduced from the observations; for the assumption of $\Delta z'+\Delta z=k C$ gives $kC=C+180°-(z+z)$, whence

$$1-k=(z'+z-180°) \div C. \qquad (b).$$

A mean value of k, deduced in this manner from a number of reciprocal observations, may be substituted in the equation (a) for finding the difference of the heights of two stations when the zenith distance has been observed at one of them only. But when z' and z are both observed, the difference of altitude is obtained independently of the value of k; for on substituting the value now given of $1-k$ in equation (a), we get

$$h'-h=d \tan \tfrac{1}{2}(z'-z). \qquad (c).$$

The absolute height h of the first station is usually found by levelling from the surface of the sea at half-tide. But assuming the refraction to be known, the absolute height of a station may be determined by observation of the zenith distance of the sea horizon. The formula is

$$h=\tfrac{1}{2} r (1+\tfrac{1}{2}k)^2 \tan^2 (z-90°). \qquad (d).$$

In the application of the preceding formulæ, it is necessary to attend to the height at which the instrument was placed with respect to the signal, or point for which the calculation is to be made. For instance, if the object observed is the surface of the ground, and the instrument is placed at the height of n feet above the surface at both stations, then on computing the coefficient of refraction from the formula (b), the angles z' and z must be each diminished by the number of seconds in the angle subtended by n feet at the distance d, that is, by $206264''{\cdot}8\ n \div d$. In the formula ($c$), which applies to reciprocal observations, the height of the instrument need not be regarded, provided it be the same with respect to the signal at both stations. In the cases to which (a) and (d) apply, the correction is made by subtracting the height of the instrument above the ground from the results given immediately by the formulæ.

The surest determination of altitudes is that which is given by reciprocal observations; for in this case the only assumption involved in the formula is, that the refraction is the same at both stations; and if the observations are made under similar atmospheric circumstances, this cannot well be supposed to lead to error. Such observations also give a more certain value of the coefficient of refraction than can be deduced from the astronomical theory, which, besides the hypotheses necessary for connecting the variation of temperature with the altitude, assumes also (for the present purpose) that the variation of temperature follows the same law throughout the whole distance from the one station to the other. The mean value of k, deduced by Bessel from reciprocal observations made during the measurement of the Prussian arc, was 0·1370; Gauss found 0·1306; Caraboeuf, from the French triangulation in Piedmont, 0·1285: Struve, in Russia, 0·1237; Delambre and Méchain, 0·1566; and in the English survey the definitive value of k was found to be 0·0809 for rays crossing the sea, and 0·0750 for rays not crossing the sea.

We shall conclude this article with a short statement of some of the more important results relative to the figure and dimensions of the earth which have been deduced in recent years from a discussion of arcs of the meridian and of parallel.

In the 'Encyclopædia Metropolitana' (art. 'Figure of the Earth'), Mr. Airy has discussed fourteen arcs of the meridian and four arcs of parallel. The results obtained by him are—

$$a=20{,}923{,}713 \text{ feet.}$$
$$b=20{,}853{,}810 \quad ,,$$
$$\epsilon=\frac{a-b}{a}=\frac{1}{299{\cdot}33} \text{ feet,}$$

a, b, denoting the semi-major and semi-minor axes of the terrestrial spheroid, and ϵ the ellipticity or compression.

In the 'Astronomische Nachrichten,' Nos. 333 and 438, Bessel has given an elaborate discussion of the figure and dimensions of the earth, founded on ten arcs of the meridian.* His final results present a remarkable accordance with those obtained by Mr. Airy. They are—

$$a=20{,}923{,}600 \text{ feet.}$$
$$b=20{,}853{,}656 \quad ,,$$
$$\epsilon=\frac{1}{299{\cdot}15} \quad ,$$

---

* In 1841

Colonel Everest, in his 'Account of the Measurement of Two Sections of the Meridional Arc of India, &c.,' has deduced the elements of the earth's figure from a discussion of twelve arcs of the meridian. His final results are—

$$a = 20{,}920{,}902 \text{ feet.}$$
$$b = 20{,}853{,}642 \quad ,,$$
$$\epsilon = \frac{1}{311{\cdot}04} \quad ,,$$

In the 'Account of the Principal Triangulation, &c.,' relating to the Ordnance Survey of the British Isles, Captain Clarke has investigated the elements of the spheroid which most nearly represents the surface of Great Britain. The following are the final results obtained by him :—

$$a = 20{,}927{,}005 \text{ feet,}$$
$$b = 20{,}852{,}372 \quad ,,$$
$$\epsilon = \frac{1}{280{\cdot}4} \quad ,,$$

From these elements Captain Clarke has deduced the following results :—

1. Radius of curvature of the meridian

$$= 20{,}889{,}705 - 111{,}949 \cos 2\lambda + 250 \cos 4\lambda.$$

2. Radius of curvature perpendicular to the meridian

$$= 20{,}964{,}404 - 3745{\cdot}0 \cos 2\lambda + 50 \cos 4\lambda.$$

3. Radius of parallel

$$= 20{,}945{,}679 \cos \lambda - 18{,}700 \cos 3\lambda + 25 \cos 5\lambda.$$

4. Length of a meridian arc whose amplitude is ϕ and mean latitude λ

$$= 20{,}889{,}705\, \phi - 111{,}949 \sin \phi \cos 2\lambda + 125 \sin 2\phi \cos 4\lambda.$$

5. Length of a degree of the meridian

$$= 364{,}594{\cdot}1 - 1953{\cdot}8 \cos 2\lambda + 4{\cdot}4 \cos 4\lambda.$$

6. Length of a degree of longitude

$$= 365{,}571{\cdot}0 \cos \lambda - 326{\cdot}4 \cos 3\lambda + 0{\cdot}4 \cos 5\lambda.$$

These formulæ are, of course, applicable only to the surface of Great Britain.

In the work above cited, Captain Clarke has also investigated the elements of the earth's figure by a discussion of the totality of trustworthy arcs of the meridian hitherto measured on the earth's surface (with the exception of Mr. Maclear's arc). The following are the final results :—

$$a = 20{,}926{,}348 \text{ feet.}$$
$$b = 20{,}855{,}233 \quad ,,$$
$$\epsilon = \frac{1}{294{\cdot}26} \quad ,,$$

These elements give for the radius of curvature of the meridian the following expression :—

$$\rho = 20{,}890{,}805 - 106{,}678 \cos 2\lambda + 227 \cos 4\lambda.$$

And for the length of a meridian arc whose amplitude is ϕ and mean latitude λ, the following value :—

$$s = 20{,}890{,}805,\ \phi - 106{,}678 \cos 2\lambda \sin \phi + 113{\cdot}5 \cos 4\lambda \sin 2\phi.$$

From the same elements the value of a mean degree of the meridian is found to be

$$= 364{,}613{\cdot}33 \pm 3{\cdot}0 \text{ feet,}$$

whence the length of the ideal mètre

$$= 39{\cdot}37840 \pm {\cdot}000324 \text{ inches.}$$

Captain Clarke has subsequently shown ('Monthly Notices of the Royal Astronomical Society,' vol. xix., page 36) that the introduction of Mr. Maclear's value of the Cape arc into the investigation does not sensibly modify the final results.

The most recent investigation of the figure of the earth is due to General Schubert. ('Essai d'une Determination de la veritable Figure de la Terre, Mem. de l'Acad. Imper. de St. Petersbourg,' vii. serie, tome i., No. 6; 'Monthly Notices of the Royal Astronomical Society,' vol. xx., page 104.) His investigation is based upon eight arcs of the meridian, in which the longitudes are measured eastwardly from an imaginary meridian 20° west of Paris.

	Latitude.			Longitude.
Russian arc	45° 20′	to	70° 40′	44° 23′
Indian arc	8 10	,,	20 31	95 20
French arc	38 40	,,	51 2	20 0
Cape arc	−29 44		−34 21	36 9
Peruvian arc	0 3	,,	−3 5	298 44
Prussian arc	54 13	,,	55 43	38 10
English arc	50 37	,,	60 50	17 40
Pennsylvanian arc	38 27	,,	39 56	300 10

Combining these arcs two and two, General Schubert obtains twenty-eight different sets of elements exhibiting great discordances. He is thereby led to suspect that the earth is not a solid of revolution. If this surmise be correct, then all comparisons of arcs of meridian under different longitudes are inadmissible. Assuming the terrestrial meridians to be ellipses and the minor axis to be constant for all meridians, he proceeds to determine the value of the minor axis by a comparison of two different sections of the same arc. Treating the Russian arc and the Indian arc in this way, he obtains two different values of the minor axis agreeing nearly with each other. The mean of the two results gives 3,261,468 for the number of toises contained in the polar semi axis.

With this value of the minor axis General Schubert investigates the major axes of the meridians of the Peruvian, Russian, and Indian arcs. The following are the results obtained by him :—

	Longitude.	Toises.
Major axis of Peruvian meridian	298° 44′	3,272,383
,, Russian ,,	44 23	3,272,650
,, Indian ,,	95 20	3,272,581

Assuming the terrestrial equator to be an ellipse, General Schubert calculates its elements from the foregoing three radii vectores, and thus finds,

Major semi-axis 3,272,671 ; its longitude 58° 44′ or 238° 44′
Minor semi-axis 3,272,303 ; its longitude 148° 44′ or 328° 44′.

The combination of these with the polar meridian gives $\frac{1}{292}$, and $\frac{1}{302}$ for the values of the ellipticity of the two principal meridians.

With these elements General Schubert computes the radii of the equatorial ellipse corresponding to the different arcs. These radii are of course the major axes of the respective meridians. With the arcs computed from these elements, and the astronomical differences of latitude, the geodetic measures are compared. The residual differences are as follows :—

Arc of Meridian.	Geodetic amplitude.—Astronomical Amplitude.
Peruvian arc	+ 0″·077
Pennsylvanian	−6 ·687
English	+0 ·736
French	−1 ·607
Cape of Good Hope	−0 ·442
Prussian	+1 ·267
Russian	−1 ·289
Indian	+1 ·619

The Pennsylvanian arc was measured entirely with rods; it is not entitled to any confidence. In the Indian arc no account is taken of the disturbing influence produced by the attraction of mountains.

For the values of the terrestrial ellipticity deduced from oscillations of the pendulum in different latitudes, and from the theory of the moon's motion, see the articles PENDULUM and MOON.

GEOGRAPHY (a term derived from the Greek *γεωγραφία*, *geográphia*) is a science the general object of which is to describe the surface of our globe. Its more special object is to ascertain and describe such physical peculiarities in each country as tend to promote or retard the increase of population and the arts of civilised life.

The political condition of a nation and the changes to which it is subject are in a great degree dependent on the character of the country which it inhabits, or of those countries which surround it. The difference in civilisation observed in nations living near one another may also in a great degree be ascribed to the same cause. Accordingly we find that as soon as men began to apply themselves to the explanation of such changes and differences, they were obliged to look to the particular character of the countries inhabited by those nations whose history it was their object to investigate. Geography is coeval with history. It is as impossible to form a just idea of the events which have been most decisive in the history of a nation without a knowledge of their country, as it is to understand the movements of two armies on a field of battle without knowing the nature of the ground which is the scene of their operations.

The first traces of anything like a geographical system, in the literature of the western world, occur in the Homeric poems. According to the Rev. Mr. Bevan, the learned author of the department of Ancient Geography in the 'Manual of Geographical Science,' we should be warranted in saying, that these represent the state of geographical knowledge down to the commencement of the 9th century, B.C. "Not that there is any methodical exposition of the views of the age on this subject," says Mr. Bevan; "the nature and matter of the poems would not admit, nor lead us to expect, as much; but the incidental notices are numerous enough to enable us to picture to ourselves the world as Homer conceived of it, and have therefore obtained for him the reputation of being the first geographer. . . . . . Homer, like many of his successors, was totally ignorant of the *spherical* form of the world; he conceived it to be a flat circular body, the upper face of which was the habitation of *men*, while the lower was the region of Tartarus, the abode of the punished *gods*. Over the earth stretched the vault of heaven, and round it flowed incessantly the stream of ocean. The heaven rested in its extremities on the surface of the earth." The ocean which surrounded the earth like the rim of a shield, is always spoken of as a *river* or *stream*, differing in character from all other bodies of water, and yet the parent of them. The land of Hellas was deemed the centre of the world's circle. The continents are not distinguished as such, nor are they designated by any general names; for Asia applies only to the upper valley of the river Caïster; and Europe seems to be confined to Greece, north of Peloponnesus. Libya signifies a part of the African coast west of Egypt. We also read of the land and river of Egypt (the name of Nile does not yet occur), with the ancient Thebæ and the isle of Pharos.

In the third volume of 'Studies on Homer and the Homeric age,' by the Right Hon. W. E. Gladstone (1858), is an elaborate investigation, under the head of 'Thalassa: the outer Geography of the Odyssey,' of the terrestrial system of Homer, of which he has constructed a map accompanying the volume. He infers, however, that in Homer's estimation the form of the world was not circular, but oval, having a shorter diameter from east to west than from north to south. In the map it has the form of a parallelogram with rounded angles, equally satisfying the condition of unequal diameters, and agreeing with the oblong form of the shield in the time of Homer; our information respecting the figure attributed to the earth being derived by implication from the form of the shield of Achilles. The outer geography consists, first, of a great mass of fabulous and imaginative geographical elements; and, secondly, of certain forms of sea and land, genuine, and though wholly or partially misplaced, yet recognisable by their general likeness to their originals in nature. The Greek world of geography proper, as described above, is the inner one. The whole strongly reminds us of the Chinese map of the world.

In the age of Hesiod (800 B.C.) the knowledge of geography had considerably extended, particularly towards the west, a general improvement in the notions of European localities having taken place; the Nile also is mentioned under its proper name, and the south of (the ancient) Africa had become the recognised abode of the Æthiopians, whom Homer had placed in the east and west. The close of the 7th century witnessed the first essay at maritime discovery, in the well-known attempt of the Phœnicians to circumnavigate Libya; but the circumnavigation of Africa always remained a problem to the ancients, much in the same way that the north-west passage has been to navigators in modern times. The merit of the discovery of the *spherical* form of the earth is due to the Pythagoreans, who came to that conclusion from astronomical observations, but whether Pythagoras himself was aware of the truth is uncertain; it was not received generally in Greece until the age of Plato. The logographers, or legend-writers, now contributed most signally to the advance of practical geography by the descriptions they gave of various quarters of the globe. There were many others who wrote accounts of their own travels, among whom was Himilco, "whose narrative," says Mr. Bevan, "is to a certain extent preserved to us in the works of Avienus. He discovered the British isles, Albion, and Ierne, and mentions the Œstrymnrides, *Scilly Islands*, which he calculated a four months' voyage from the coast of Tartessus." In the works of Æschylus we find the opinions of the age in which Herodotus lived, before his geographical system had been accepted. They represent the world as a circular (?) body, with Delphi in the centre, surrounded by the ocean, which is rightly deemed a sea, and not a river. In place of the *two* sides of the world, we hear of the *four* quarters, north, south, east, and west. We further find that he adopted the division of the land into three continents; the river Phasis separating Asia, and the Straits of Hercules Libya, from Europe.

Herodotus, the father of history, is likewise the father of geography, in the sense that his writings formed the commencement of a more real and enlightened system, the materials of which, as will presently be shown, were drawn from actual observation and scientific research. His geographical descriptions are short and general, but always clear, and sufficient to show how far the physical peculiarities of each country influenced the changes and events which he had undertaken to commemorate. When he found that a country was characterised by striking peculiarities, he described them at considerable length. Instances of this are his description of Egypt in the second, and his description of the Scythians and their country in the fourth book.

From the preliminary chapters on the life and writings of Herodotus, prefixed to the new English version of his history, by Mr. Rawlinson (1858), it appears that his active and inquisitive turn of mind led him at an early age to engage in travels, the extent of which, combined with their leisurely character, clearly shows that a long term of years must have been so occupied. Herodotus visited Babylon, Ardericca near Susa, the remoter parts of Egypt, Scythia, Colchis, Thrace, Cyrene, Zante, Dodona, and Magna Græcia; thus covering with his travels a space of thirty-one degrees of longitude (above 1700 miles), from east to west, and twenty-four of latitude (1660 miles) from north to south. "Within these limits, moreover," Mr. Rawlinson observes, "his knowledge is for the most part close and accurate. He has not merely paid a hasty visit to the countries, but has examined them leisurely, and is familiar with their scenery, their cities small and large, their various wonders, their temples, and other buildings, and with the manners and customs of their inhabitants. The fulness and minuteness of his information is even more remarkable than its wide range, though it has attracted less observation. In Egypt, for instance, he has not contented himself with a single voyage up and down the Nile, like the modern tourists, but has evidently passed months, if not years, in examining the various objects of interest." In fact, to whatever extent he was indebted to earlier authorities for his preparatory culture, the real source of almost all that he has delivered to us in the shape of geographical description, was personal observation and inquiry. His accounts of countries are, in the great majority of cases, drawn from his own experience, and are full or scanty according to the time which he had spent in the countries in making acquaintance with their general character and special phenomena. Where he has not travelled himself, he trusts to the reports of others, but only, to all appearance, of eye-witnesses. If in any case he gives mere rumours which have come to him at second-hand, he is careful to distinguish them from his ordinary statements and descriptions. He seems to have been indefatigable in laying under contribution all those with whom his active and varied life brought him in contact, and deriving from them information concerning any regions unvisited by himself, with which they professed themselves acquainted." By these means, concludes the latest interpreter of, and commentator upon, Herodotus, "he gathered the materials for the geographical portion of his work."

There is, however, something vague in the descriptions of Herodotus, for want of a means of referring to the position of places as determined by astronomical observations. Herodotus, indeed, was apparently not fully acquainted with the state of science, and particularly astronomical knowledge, as it existed in his age. Thales had some time before calculated an eclipse of the sun, and from his epoch astronomy attracted the attention of the Greek philosophers, and facts in this science began to accumulate. It was, however, soon evident that most of these facts lost a great part of their value, from the circumstance of the position of places not being ascertained. Astronomers, therefore, were led to devise a method of fixing the latitude and longitude of a place; and though this method, when compared with our practice, was extremely rude and imperfect, yet it must be considered as having materially contributed to the improvement of geography. With the help of such astronomical observations as were made by his predecessors or himself, Eratosthenes formed the first system of geography founded on a basis which in some degree approached to truth. He determined the geographical position of a great number of places, many of them hardly known to Europeans; but these determinations were often founded on vague information, and consequently were in a great degree conjectural. Still his map gave a much truer image of the figure of the world than philosophers had formed before him, as he took care to subject his information to a strict examination.

While his successors were slowly improving his work, the historians, following up the plan traced by Herodotus, enriched geography with the description of those countries which at the time of the historian of Halicarnassus were not known, or at least only imperfectly known in Greece. Among these historians Polybius deserves particular mention. His geographical descriptions of the countries which inclose the western portion of the Mediterranean Sea are as good as, if not superior to, those by Herodotus of the countries between the Caspian Sea and the Gulfs of Persia and Arabia. About this time, or shortly afterwards, it would seem that several persons undertook travels into remote countries, in order to investigate their physical character, and to ascertain the accuracy of such information as had reached them by hearsay. The most conspicuous among these adventurers was Posidonius. Like Alexander von Humboldt, he went to the then remotest accessible part of the earth, to Iberia, which was as noted for its mines of the precious metals as South America and Mexico are in our times; and though only a small portion of the information which he collected has come down to us, he seems to have paid great attention to nearly all the objects of inquiry which the German philosopher has investigated.

The geographical information collected by these eminent travellers and many others of less note was scattered over a great number of works, access to which, in the circumstances of those times was necessarily difficult. Strabo, a native of Asia Minor, who wrote in the time of Augustus and Tiberius, undertook to incorporate in one work those scattered materials, and to add the information which he had acquired in his own travels. His object, according to his own declaration, was to compose a work which should be useful to those employed in the administration of countries. He accordingly discarded everything which was only of temporary importance, and described each country according to its permanent physical character. In a few words he informs his reader of the extent of each country under description, and its chief political and historical divisions. Passing on to the detailed description of these divisions, he follows much more nearly the course of our modern travellers than that of our geographers. Mountains, plains, valleys, rivers, and towns keep their true position with respect to one another; productions and climate are mentioned in their proper place. A few short observations on the commerce and the articles of export conclude his description. By this judicious arrangement the sagacious Greek geographer avoided causing to his readers that weariness which every one experiences in perusing common geographical books, in which every object is, as it were, rooted out from its natural place and transported to a foreign spot. We cannot help thinking that the method of treating geography adopted by Strabo ought still to be considered as a model, and ought to be again introduced into works of this class: the late Charles Ritter, in his justly esteemed geographical works, strictly adheres to the plan of Strabo.

Whilst the geography of Strabo was extensively used all over the Roman world, the astronomical school of Alexandria continued collecting materials for the purpose of completing and perfecting the system of mathematical geography framed by Eratosthenes. These collections enabled Ptolemy to form his Geography, which is hardly anything else but a catalogue of places according to their estimated or determined geographical position. In its time it was certainly a very useful work, but its value to us consists chiefly in showing how far the Greeks had carried their knowledge of the surface of the globe. From the time of Ptolemy up to the 14th century scarcely anything was added to what he left behind him.

The downfal of the Roman Empire, and the occupation of Western Europe by barbarous nations who were hardly acquainted with the elements of civilised life, suddenly extinguished all scientific research. Many centuries elapsed before these nations made such progress in civilisation as to enable them to turn their attention to science. Geography, which shared the fate of the other sciences, was, however, revived sooner than the rest, and the circumstance which led to this was the publication of the travels of the Venetian, Marco Polo. Though his accounts were rejected by his countrymen as mere fictions, or at any rate were treated as great exaggerations, some German scholars at Nürnberg took a different view of them. As Nürnberg at that time was one of the greatest trading places on the Continent, and for that reason closely connected with the first commercial houses of Venice, these learned men soon procured a copy of Marco Polo's travels. For the other countries of the world, taking Ptolemy as their basis, they introduced the principal geographical facts contained in Polo's travels into their globes and maps, as an addition to the knowledge transmitted by the astronomers of Alexandria. But Marco Polo had made no astronomical observations, nor had he even mentioned the length of the longest day at any place. The German geographers were therefore obliged to determine the extent of the countries which he had traversed by his vague estimates of days' journeys; but the length of these journeys was greatly exaggerated by them, as they were entirely unacquainted with the peculiar character of Eastern Asia. The consequence of this was, that on their maps and globes Asia extended over the whole of the Pacific, and its eastern shores were placed very nearly where the Antilles are situated. This error of the geographical school of Nürnberg was attended with very important consequences. Columbus, relying on their estimates, considered that the shortest way to arrive at the eastern parts of Asia would be by sailing to the west. He found America; but the same school of geographers whose errors had induced him to venture on such a voyage deprived him also partly of the honour due to his great discovery. Baron von Humboldt proved that the very slow and insecure communications which then existed between Spain and Germany brought the news of the discovery of the New World to the geographers of Germany, with the names of Columbus and Americo Vespucci together, and that the Germans thought that Americo was the true discoverer of the new continent, which accordingly obtained from them the name of America, a name that has become universal.

The details of this subject will be found in Humboldt's elaborate work entitled 'A Critical Examination of the History of the Geography of the New World, and of the progress of Nautical Astronomy in the 15th and 16th centuries.' It is an immense digest of the geographical information of the later periods of classical antiquity and of the middle ages as well as of the times to which it more expressly relates. Many important results of the investigation have also been given by the author in his 'Cosmos.'

The first half of the 16th century was entirely employed in discovering the extensive coasts of America, and the countries and islands lying along it, and in the Indian Ocean; and geographers were fully employed in inserting these new discoveries in their maps according to such determinations of positions as they could obtain. In all the geographical works written during that century this characteristic is observable. They resemble much more the geography of Ptolemy than that of Strabo. But what could geographers then know of the interior of countries whose very coasts were yet hardly laid down with accuracy even in a few places!
